No. 13. JANUARY 1909.
I.-A Case of Almormal Oviducts in Homarns vulgaris. By W. G. Riderrond, D.Sc., Lecturer on Biology at St. Mary's Hospital Medical School, London.
The lobster which forms the subject of the present note was given me by Dr. W. T. Cahman, carcinolugist at the British Museam, whom I have to thank not only for the specimen, but also for information respecting the literature of abuormal genitalia in the higher Crustacea generally. The specimen was sent to the Museum from Billingsgate Fish Market, and was stated to have been canght off the Orkney Isles.

On the right side of the buly the normal oviducal aperture is present on the base of the third or antepenultimate leg (fig. $1, a$ ), but on the left side there is no aperture on the third leg; instead there is an opening on the basal joint of the fifth or last leg (where the vas deferens of the male normally opens), and another aperture on the fourth leg. (fig. 1, $c \& b$ ).

Abnormalities in the generative system of the lobster (Homarus vulyaris) are apparently very rare, although in the Norway lobster or Dublin prawn (Nephrops norvegicus) and in freshwater crayfishes they occur with comparative fiequency.

Ann. \& Mag. N. Mist. Ser. 8. Vol. iii.

In $N^{\top}$ epherops it is no uncommon circumstance for additional genital apertures to be present. F. II. A. Marshall*, writing in 1901, records how, on an examination of 1000 male specimens, he found $12 \cdot 2$ per cent. aboormal in having supernumerary genital openings, and more recently I). C. M:Intosh $\dagger$ examined 4429 males, and found that 287 were

Fig. 1.

Thintral wiew of the hases of the last three thoracic lugs. u, afperture on the hase of the third leor on the bight side : $b$ and $c$, the apertures on the fourth and tifth leres on the left side. Two-thinds natural size.
abmormal, a percentage of $6 \%$. In none of these specimens were the usual ducts on the last pair of walking-legs wanting, the abnormality invariably consisted in the occurrence of genital ducts in addition to the normal pair. These specimens were caught in the Firth of Forth and Moray Firth. Of 319 males captured in the Clyde, II'Intosh found $2 \cdot 5$ per cent. to he abnormal in having supernumerary genital openings. In no female specimen examined by him was any almormality olsserved, either in the position or the number of the apertures, a truly remarkalile circumstance in view of the large percentage of abnormal cases among the males. Marshall $\ddagger$, however, mentions one case in which, in addition to the normal oviducal openings on the third or antepenultimate walking-legs, there were a pair of apertures on the last walking-legs.

Mr'Intosh makes no mention of the manner in which the

* Marshall, F. II. A., Proc. Zool. Soc. Lond. 1902, i. pp. 2-12.
+ M'Intnsh, I). C., I'toc. Lioy. Plysical tioe. Edin!\}. xvii. 4, 1908. pp. 129-142.
$\ddagger$ L. c. 1,6 .
supernumerary vasa deferentia of Nephrops were connected with the testes, but Marshall * states that in some of the abnormal males examined by him the apertures opened internally into blind sacs, in others the connection, partial or complete, between the testis and the supernumerary aperture was by means of a branch of the normal vas deferens belonging to the last thoracic somite.

As regards the European craytishes of the genus Astacus, the gonad is sometimes hermaphrodite $\dagger$, and females are known sometimes to bear on the first abdominal somite large appendages like those of the male instead of the usual vestigial structures $\ddagger$. Desmarest § records a female $A$ stacus with supernumerary orifices on the fourth or penultimate legs, and oviducts which on each side forked downward so as to become connected with the apertures on both third and fourth legs. A somewhat similar case is given by Benham!!, only in this animal there were on each side tiwo ovidncts, opening on the third and fifth less. Bateson of mentions twenty cases of female crayfishes having a unilateral supernumerary opening on one of the fourth less; he also cites one case with additional oviducal openings on both of the fourth legs, one case with extra openings on both fourth and fifth legs, and eight cases in which the oviduct was suppressed on one side, so that the a:imal had but one oviduct in all. Ahnormalities in the males are much less common than in females, for Bateson found only one abnornal male in 714; this one departed from the normal in the suppression of the lower part of the vas deferens, and its external opening, on one side of the body. In most of the twenty females with an additional oviducal aperture on one of the fourth legs, the oviduct on the abnormal sile of the body was in the form of an inverted Y , as in Desmarest's case.

* Limuberg, E., Zool. Anzeiqer, xxi. 1598, pp. 3:3t-39.7 and pp. :3.5:2, For other observations on supermumerary enital oritices in P'arusturus see rom Martens, E., Bitz.-Ber. Ges, naturf. Fr. Berlin, Ľī̀, p. :3; won Ihering, II., C'mgres Iuternational de Zoologie à Mocen, Lsoz, part ii. (1893) pp. 43-49; and Faxon, W., Proc. U.S. Nat. Mus. xx.

fish, the ere are regularly two pairs of genital ducts, one leading from the gonad to the coxal joints of the third pair of leces and the other to those of the fifth. In the male the anterion duct is somewhat narrower than the other and does mot really open to the exterior, the "orifice" on the thitrd lees not beinis patent. In the female the posterior cluct is comsiderably thimer than the anterior ; it is ton narmew to allow of the passage of ora, and ends blindly on the enxoporlite of the fifth leg. There are thus vestigial oviducts in the male and vestigial vasa deferentia in the female. I immbere formd in the testis lage bodies resembling ova, and he is inclined to regard the species as exhibiting a partial structural, but mot functional, hermaphroditism.

In Cimhlarus, a Nonth American Astacil, Faxon* has observed four cases in whele external fiatures of the two sexes are combined in the same individual; and limmbergt speaks, with some lesitation, of rudimentary ducts passing to the third legs in two males.

In Cherols pmeissio, an Anstralian cray fish, von Martens $\ddagger$ has descrited three males with alditional mifiess on the third pair of legs; there were no tuhes comecting these openings with the gonad.

In the Indian deep-sea species of the family Axiide it is common to find in adult females orifices corresponding with the genital orifices of the male $\S$.

In male specimens of a Pacific hermit-crals, Pugurus deformis, supernumerary apertures on the third or antepenultimate legs seem to be regularly present If, alhoong Borradaile mentions a case in which the sumemumerary aperture was absent on one side of the body.

In the lohster, Homarus vulgaris, abnomal genitalia are very rare, if one may judge from the pancity of recorded cases of abnomality. Nicholls $\%$ in 1730 described a case of complete hermaphroditism in a lobster, the left side of the gonad being testicular, and furnished with a duct leading to the last walking-leg, and the right half being ovarian, with

a duct to the third or antepenultimate leg ; and Herrmann *, in 1890 described the presence of ova in the fore part of the testis of a lobster.

Fig. 2.

Dissection of the ovary and its ducts, seen from abowe. a, the duct to the third leg on the right side; $b$ and $c$, the ducts to the fourth and fifth legs on the left side. Two-thirds natural size.
In the case under consideration there is no question of hermaphroditism, in spite of the fact that one of the three ducts opens in the position of the vas deferens of the male. The specimen is clearly a functional female, since it carries, numerous ova attached to the abdominal appendages. The first pair of abdominal appendages differ in no respect from those of the nomal female, and the sternal pouch or seminal receptacle, between the bases of the last two pairs of legs, is

* Herrmam, (i., Bull, sci. France et Belg. xxii. 1890, p. 43.
exactly as in a normal female. Of the three apertures the first and second, on the third leg of the right side and the fourth leg of the left (fig. 1, a \& $Z$ ), are dark in colour and with a hairy front edge. The third opening, on the fifth leg of the left side (fig. $1, c$ ), is pale in colour ; it has no hairs and is rather more raised than the first and second apertures, but its hind edge is mot so elevated as is that of the opening of the vas deferens of the male. The third opening is very slightly smaller than the other two. All three are patent.

The ovary is fully ripe, and a microsequic examination of portions of the anterior and posterior ends fails to show any evidences of hermaphroditism. The duct to the third right $\operatorname{leg}(f i g .2$, a) arises fimm the right side of the ovary at about the same distance behime the ovarian bridge as in a normal female. The duct on the left side to the last leg arises from the left side of the ovary at a more posterior level (fig. $2, c$ ). The tube is exactly like a normal oviduct, gently tapering, and without any differentiation of middle glambluar sement and terminal ejaculatory segment that one finds in the vas deferens of the lobster *.

The duct to the penultimate leg of the left side (fig. 2, l.) could not be traced in its entirety, owing to the fact that in the interval between the death of the animal and the dissection of its body the liver had exerted a digestive action upon the surrounding parts, particularly in the regions represented in fig. 2 by the dotted lines. There is no indication that the duct to the fourth leg arose as a branch from the duct to the fifth leg; if it existed at all it must have come direct from the gonad. The lower part of the duct (the part near the letter $b$ in fig. 2 ) is as wide as the corresponding part of the other two ducts, and like them contains ova, so that there can hardly be any doultt that the duct was a functional oviduct, and not a short tube cnding blindly internally.

The specimen is deemed worthy of description, partly because of the scarcity of recorded cases of abnormality in the genitalia of the lobster, partly becanse the specimen was sufficiently fresh for the relations of the internal parts to be ascertained, and partly because, as I have urged before $\dagger$, it behoves one to place on record cases of abmormality, even though as solitary instances they may be of no particular interest, in order that it may be possible for later writers to

[^0]collate the recorded examples and gain some insight into the general principles underlying the irregularities．

Since the above was written，Dr．Calman has shown me a living specimen of the edible crab，（＇ancer pagurus，with no oviducal aperture on the left side．All the other external features of the animal were as in the normal female．

> II.-Description of a new Lemonia. By the Hon. Walter Rothschild, Ph.D.

Lemonia taraxaci terranea，subsp．n．
This very distinct local form was taken by Di．Jordan and myself at Le Lautaret，Hautes Alpes，in Angust 1908，at light．We secured nine specimens，all males．

ठ．Differs from L．taraxaci taraxaci in having all the wings brownish clay－colour instead of dull yellow．Thorax brownish orange ；anteme yellow ；abdomen black above， orange below．Wings below as above，only paler ；tringe orange－buff．Some specimens are also paler above than the type，with the costa broadly buffish．

$26.8 .27 .=842$. R. Parle to ('ubatá\%. (As 731.) A label on this specimen bears Westwood's number "Nymp. 7!," and the frollowing note in his haml-writing:-_"Eub. cœenus, \& vel var."
$21.111 .27 .=843$. Mriap, inte to S. Joarquim (Joar. Alves). Rza. a. 24. S. 25. $=844$. Retion. "All at the rivulet near the house at Retiro." Between Goyaz and Jeraguá.
20. 9. 29. $=845$. Pará. S.E. of S. Jozé.

Westwood's list (N. 79) agrees.

## Eubagis (Dynamine) cœnus, F.

4. 11. 2.\%. $2=846.84 \%$. Minas (ieraës. (1s 559.)
liz. 11. 1. 27. $=848$. Cubatão.
Jiz. 1. ¿. 2̈. $=849$. "On the mad." Between Juntliahy and Capivarý.
lB. + 2. $-2-2=850$, 851. Ollania to Ro Paran.
2.) ネ.2. $2=852,853$. As above. A label on 852 bears Westwood's number N. 80, and the following note in his handwriting:-"Eub. Ccenus, Donov. Ins. Ind."
a. 2́t. と. 27. $2=354.855$. R. P'ardo to Cubataio. (As 734 .) Westrood's list (N. SU) agrees.

## Eubagis (Dynamine) athemon, Linn.

Baz. 361. I. [15. [10. 25.] $=856$. Minas Geraë: " $I^{\prime}$ [umelio]. At the Discohérto do Autonio Velho."
28. 11. 25. $2=857$, 858. Minas Geraës. $\quad(1=635$.) No. 858 hears Wiswoml's mumber "Nymph. is."
Westwood's list (N. 78) agrees.
Eubagis (Dynamine) tithia, Hübn.
$B z+100 \%$. I. 27. 10. 2\% $=859$. Minas Geraëz. " $P[a-$ pilio]. At San Juño de Acpomucéna and on the rual from Discoberto."
10. 11. 25. $=860$. Minas Geraës.

1'z. + a. 26. 8. $2 \overline{2} .=861$. R. Pardo to C'ubatáo. (A; 734.)
30. 10. 2 2. $=862$. Sapezal in Conceiçaio. This specimen bears Westwood's number N. 83.
Westwood's list (N. 83) agrees.

## Eubagis (Dynamine) glauce, Bates.

a. 24. 8. 28. $\delta=863$. Retiro. "All at the rivulet near the house at Retiro." (As 844.)
Westwood's list (N. 98) agrees, and the number, "Nym. 98," is also borne by 863.

This specimen is unfortunately in very bad condition, thus rendering determination rather difficult. However, on comparing with specimens in the Gorlman-Salvin Collection and with Bates's description in the 'Journal of Entomology', ii. 1. 324 , it seems nearly certain that the species is $E$. glunce.

Eubagis (Dynamine) mylitta, Cram., = postverta, Cram. 28. 10. 25. $\delta^{\top}=864$. Minas Geraës. (As 635.)
$24.12 .25 . \delta=865$. Rio de Janeiro. Aqueduct (on the first hill on the left). This specimen bears Westroud's number N. 84.
31. 12.25. $q=866$. Rio de Janeiro. (As 668.)
10.1.26. 2, $\delta^{*} \&=867,868$. Rio de Janeiro. Práia Gránde and S'. João de Carahý. 868 bears Westwood's number N. 82. (As 670.)
Bz. 13. 3. 26. $\delta=869$. "Aqueduct." Rio de Janeiro.
B3z. 15. 3. 26. i $=870$. "Catombi." Rio de Janeiro. "Catombi, in plantis."
22. 3. 26i. $\%=871$. Lio de Janeirn. Along the [Curioca] Aqueduct, to the head of the Valley of Laranjeiros.
Bz.22.3.26. $\quad$ ¢ $=872$. Rio de Janero. (As 871.)
Bz. 3. 4. 26. $\delta=873$., Rio de Janeiro. "Along the Carioca Aqueduct."
Bz. 16. 3. 27. $\delta=874$. Between Morumbi and S. Píulo.
No males in the above series have the black spot at the anal angle of the hind wing (upperside), which is a characteristic of most of the males in the Hope Collection, especially strongly marked in two from Chapada. In the British Museum also, the majority are without it ; and in the Godman-Kalvin Collection out of a large series only a small minority have it marked-noticeably in specimens from Chapala, Curumba, Peru, and Ecuador, where it is well defined. In one specimen from Paraguay it is very strongly marked.

Westwood's list (N. 82 and N. 84) adds theee more individuals captured:-
12. 3. 26. Rio de Janeiro. "Aqueduct." (Under N. 81.), 1. 4. 26. Rio de Janeiro. "In the valley of Catumbi." (Under N. 82.)
9.5.27. S. Paulo. Near the Convénto da Luz. (Under N. 82.)

Eubagis (Dynamine) arene, Hübn.
7. 4. 29. $\uparrow=875$. Porto Réal (Naçionale). 26. 5. 29. $\delta=876$. "Silva." Between Italóca and Baião. North of the falls of Guaríba.
Westwood's list (N. 97) agrees, and both specimens bear this number.

This species is unrepresented in the British Muscum.

## Epicalia (Catonephite) acontius, Linn.

4. 12. $2 \mathrm{~s} . q=877$. Porto Real. Walk to the Igarapé.
"P'apiliones, caught in the woody campo; but the longwing[ed] one is only fomed in forests in the shanle."
As yet the incutity of "the long-winged one" has not been establisherl, inut as the working ont of the collection progresses no doubt this will become apparent.
This specimen bears W estwond's number ( N .32 ) , and his date agrees: in his list Westwoor wrote "Jjpiraliu L'ervetii, i." Epicalia pierretlii, Dbl. \& Hew., is an alnid species.

## Epicalia (Catonephile) penthia, Hew.

8. 2. 26. $\delta=878$. Organ Mtns. (In a ride to the ('attle Pounds and the Milho Roça.)
This specimen bears Westwood's number ( $\mathrm{N}, 11$ ).
Iiz. 13. :3, 26. it $=879$. Rio de Janciro.
1. 3. 26. $q=880$.

Buth these specimens bear W"estwont's number (N. 111).
a. 29.8.27. $\delta^{\top}=881$. Cérvo. (As 527.)

Westwood's list (N. 10 and N. 11) agrees.

## Nica flavilla, Godt.

Bz. 15夕. I. [8. 9. 2. $]$ ]. $=882$. Rio de Janciro. "P'(1pilio. Along the Aqueduct."
27. 1. 26. $=883$. Rio de Janeiro.
ß~. + 7. 3. 26. $2=884,885$. Lío de Janeiro. "At (Jatombí."
7. 3. 26. $2=886,887$. Rio de Janeiro. "At ('atomlíi."
9. 3. 26. $2=888,889$. Ihio de Janciro. A latuel on 889 bears Westwood's number "Nym. 9.," and the following note in his handwriting:-"Nica facilla, (iol., 4U6, Hb. Samml., Ex. Sch."
Bz. 9. 3. 26. $=890$. Rio de Janeiro.
10.3. 2ט゙. $3=891-893$.

Bz. 12. 3. 26. $=894$. "Carioca Aqueduct." Rio de Janeiro.
Westwood's list read. 12. 3. 25, an obvious slip, because Burchell did not land at Rio till 18. 7. 25.
16. 3. 26. $=895$. Rio de Janeiro. (As 647.)
21.3.26. $=896 . \quad$ " "Along the Carioca Aqueduct."
26. 8. 27. $=897$. R. Pardo to ('ul)atio. (As 731.)

This specimen bears the number N. $12^{* *}$, and is mentioner under it in Westwood's list. It is the only specimen under that number.
21. 2. 25. = 898. Goyaz. W.N.W. beyond Forca. "All in woods."
Westwood's list (N. 94 and N. 12*) agrees.
Temenis laothoü, Cram., £. ariadne, Cram.
30. 10. 25. $=899$. Ninas Geraë. " (In the forest). () ${ }_{n}$ the N.E. side of the arraial of がan Joino de Nĕpomucéna." This specimen bears Westwood's number N. 12.
4. 11. 25. $=900$. Minas Geraës. (As 559.).

These two specimens are under a separate number (N. 12) in Westwood's list.
Bz. + 25. 8. 27. = 901. Ollaría to Rio Pardo.
a. 29. 8. 27. $2=902,903$. Cérvo. (As 527.)
1.9.27. $=904$. "On the road." Veravínha to Fránca [Villa Franca].
28. 10. 27. $=905$. "In sylva." S. Joarquim to S'apezál. a. 24. 8. 28'. $=906$. Retiro. "All at the rivulet near the house at Retiro." Between Goyaz and Jeraguá.
This specimen bears Westwood's number "Nym. У3."
Bz. p. 24. 8. 28. $=907$. Retiro. (As 514.)
p. 24. 8. 28. $=908$. Retiro. (As 514.)

Instead of 906, 90'7, 908, Westwood's list (N. 9:3 except for 899,900 mentioned above) gives two specimens dated a. 24. S. 27 and p. 24. 8. 27 (the first probably mistaken for 906 , and the second for either 907 or 908 ).

In the British Museum this insect is placed as the ariadne form of luothe $\ddot{e}$; in the Godman-Salvin collection as the luothoë form of aricalne. Laothö̈ and arialne were both described by Cramer in the same work, but inasinus as aricedne appears on the later page, it would seem that leothoë should stand.

## Epiphile orea, Hübn.

9. 2. 26. $=909$. Organ IItns. (By the river Pacanué.)

Bz.p. 24. 8. 28. $=910$. Retiro. (As 514.)
Il entwool's list (N. (1) agrees, and this number is bome by both specimens.

## Libythina cuvierii, Godt.

10. 10. 27. = 911. Bomfim to Forquílho.

We-awod's list (N. 100) agrees, and his momber is on this specimen. Burchell's example is a goud deal smiller than any in the British Museum series.

## Myscelia orsis, Drury.

ljz. + S.11. 2. . $\delta=912 . \quad$ "Sylratica" on the English labeel, "Pap". -ylvat." on Erazilian latuel. Minas (xeraë10.11. 25. $\quad$ ¢ $=913$. Minas (Geraë:

Weetwont's list wives two mone of this date (imber N. 11). İz. 1056. [17. 3. 26]. $\quad \uparrow=917$. Rio de Janciro. "Along the Carioca aqueduct, and descending the high hill (mentioned 31. 1. 21;) into the Valley of ' :atombi.-But they were mostly along the Aqueluet; and only a few on the hill."
A further note on this date says:-" Papiliones. These B species frequent the worls." [i'he Satyme isutterty
 and the Nymphaline Mysedit orsis, Drury.] As yet it hat been impossible to tind ant the thind sperbies hare mentionel.
15. 3. 26.3 \% 1 \& $(920)=918$-921. Rio the Jancir. (As above.)
Westwoul's list gives altnsether two specim-nss mulo mol 10.50 (under N. 13 and N. 14), finur with 17. :3. 2is under A. 14 and one under N. 13. 919 and 921 bear Vt cotwoul's number N. 14.
18.3.26. $q=922$. Rio de Jancir". "Ahoug the Canióa Aqueduct."
20. 3. 26. $q=923$. Rio de Janeiro. "Along the C'anivea Aqueduct."
This specimen bears Westwood's number N. I3.
Westwonl's list gives arother specimen capturel on this omit the previns date. His list contains a specimen of each date under N. 1:3 and a similarly dated pair under N. 14.
21. 3. 26. $f=924$. Rio de Janeiru. "Alung the Carivea Aqueduct."
3. 4. 26. $\quad \circ=925$.
"Along the Carioca Aqueduct."

Westrood's list gives three altogether of this date, twn under N. 14 and one under N. 13.
20.9.26. $q=926$. "Sylva." Sántos. "In the forest above the Monastery of S. Bento."
26.9.26. $+=927$. Sántos. In a walk to the Chapel on Montserrát. "These Papiliones very plentiful in the woods."
Westwood's list (N. 13) includes a date, 29. 9. 26, probably an erroneous copy of 26.9.26, which is otherwise unaccounted for. Except for the above additions his li.t (N. 13 and N. 14) agrees.

## Eunica bechina, Hew.

4. 12. 28. $=928$. Porto Reál (Naçimale). Walk to the Igarapé. "Papiliones, caught in the woody campo; but the long-wing[ed] one is only found in forests in the shade." See note on $87^{17}$.
$B \approx+28.3 .29 . \quad q=929$. Purto Reál. This specimen bears Westwood's number N. $15^{* *}$.
Westwood's list (N. 15*) agrees.

## Eunica maia, F.

 $p$ [ilio]."
Westwood's list gives another of this date.
$\quad$ z. + sり6. I. 25. 10. 25. $4 \delta=931-934$. Jimas Gerä̈. "Pap[ilio]. At Discoberto, near João Pedro's house." 896. 25. 10. 25. $\delta=935$. Ninas Geraës. One of the above without the Brazilian label.
This specimen bears Westwood's number N. 15\%\%.
29. 10. 2. . $\delta=936$. Mimas Gereës. "In the forest on the S.E. side of S. João de Nĕpomucéna."
4. 11. 25. $\delta=937$. Minas Geraës. (As 559.)

Westwoot's ist (N. 15\% ) adds another specimen (anturen? 10. 10.27. Bomfim to Forquílho. He also includes the next species. His dates agree.

Eunica mygdonia, Godt.
10. 4. 28. $\delta=933$. Gnyaz. (Gmínho de Caméira. (As 733.)

Westwood's date agrees.

Eunica taurione, Hübn.
7. 11. 25. $=939$. Minas Geraë3.

Westwomi's list (N. 15) agrees, and his number is borne by this specimen.

> Eunica volumna, Godt., = tithonia, Feld.
10. 10. 27. $=940$. Bomfim to Forquíllo.

Westwonl's list (N. (t.t) agrees, and his number is on this specimen.

## Eunica caresa, Hew.

4. 11. 25. $=$ 941. Mina二 (reraï $\quad(A=559$.) We-twool'number ( N .31 ) is borne by this specimen.
Westoromi's date (mmer N. S1) agree, but lie gives the 1ame "Ifysolia sydumin." A lahid on the spacimen leans in Trestwoul's handwritig: :-"Mys. Sydonia, Gonl., 416 !"

Eunica margarita, Godt.
20. 6. 227. $=942$. "Rita." Vicinity of S. Panlo. Wéntwood's number "Nym. 96 " is on this specimen.
Westwomel's list (N. (ili) gives two specimens captured on this date.

Anartia amalthea, Linn.

 Discoobérto do Antonio Vellio."
Westwood adds another of this date.
$B=+$ 9.j. III. 2.). 10. 2.). $3=945,946,947$. Ninas (i raës. "Papilio. At Discoberto, near Joño Pedro"s homse."
14. 1. 21. $3=948.949,950$. Rin de Janeirn. ( $1=693$.
27. 1. 26. $=951$. Rio de Janeiro.
31. 1. 21. $2=952,953$. Rin de Janeiro. (As 474.)
9. $2.26=954$. Orean Mtns. (Br the river Pacaqué.)
12. 2. 26. $=955$. Organ Mins.

Bz. + a. 25. 2. 26. $=956$. "Frexaes." Organ Mins. Burchell sometimes wrote "Frexaes" for "Frechál."
a. 25. 2. 2 ́. $=95 \%$ " Frexacs." Orean IItns. See note on 956.
$B z+26.2 .26 .=958$. Organ Mountains. Near Magei. 25. 2. 26. $=959$. Organ Mountains. On the Rio Magé.

Westwood's list adds another of this date.
1.3.26. $=960$. Organ Mtns. Along the River Macé, upwards to the Fazénda da Lagóa. Westwood's list adds three more individuals captured on this date.
Bz. + 2. 3. 26. $=961$. Rio de Janeiro or Organ Mtns.
Westwood's list gives another of this date.
7. 3. 26. $2=962$, 963. Rio de Janeiro. "At C'atombí." 10. 3. 26. $=964$. Rio de Janeiro.
16. 3. 26. $\delta=965$. Rio de Janeiro. (As 64'\%)

This specimen bears Westwood's number (N. 1).
16. 3. 26. 966. Rio de Janeiro.

Bz. 15. 9. 26. $=967$. Sántos. "Papil. at edge of the forest at S. Bento Monastery."
19.9.26. = 968. Sántos.

Westwood's list gives two more individuals captured on this date.
a. 29.8.27. = 969. Cérvo. (As 52\%.)
9. 1. 28. $3=970,971,972$. Goyaz. By the Horta etc.
4. 3. 28. $5=973-97 \%$. Goyaz. "Caught hy the rio Vermelho, near the Carioca aqueduct : by C[ongo]."
Bz. 2. 2. 29. $=978$. Porto Reál. "On the western side of the Tucantins."
19.2.29. $=979$. Porto Reál.
18. 12. 29. $=980$. "in locis apertis." Pará. Rivulet above arsenal.
Form amalthea, L., in British Museum.
With the exception of 980, all the above specimens are named form rocselie, Esch., in British Museum. 'The form amalthea seems to be more prevalent in 'Trinidad, Honduras, Guiana, and Bolivia. In Colombia an intermediate form exists. The difference between them is that the subapical white bar of the fore wing of f . rocselia is replacel in f. amalthea by faint and indistinct white spots.

Westwood's list (N.1) omits 969, and adds two specimens captured respectively, 8. 2. 26, Orqan Mins., and 5.2 .29 , Porto Reál. The dates otherwise agree.
No date. $=981$. Placed by Westwood in his list of Anartia jutrophe, Limn. Considering the obvious differences between these two species, it is, perhaps, probable that Burchell's label has become displaced from the original specimen. There is no $A$. jatrophe without a date in the collection, and there is no - 1. amalthea mentioned in Westwood's list without a date.

Anartia jatrophe, Linn.
10. 1. 2f. $:,=982,983,984$. Rio de Janein. (As 670.)

Westwood's list (N. 3) makes this last date 28. 10. 26, probally a clerical error. He also places these two specimens in his list of the next species under the name of "Vanessa Hhuntera." These Burchell specimens have been compared with the types of $I^{\prime}$. myrinna, Doubl., in the British DLus un.

Pyrameis luntera, Fabr., form brasiliensis, Moore.
10. 11. 25. $=106 \%$. Minas Geraës.
6. 12. 2.). $=1068$. Rin de Janeiro. On the Coresvádo Mountain. (As 667.)
This specimen bears Westrood's number N. 3.
7. 6. 27. $=1069$. Vicinity of S. Paulo.

Westwoo i's list (N.3) gives two more specimens, one captured 4. 11. 25), Minas Geraës (as 559), and one 20.6.27, S. Paulo. He names it Vanessa huntera.

Mr. E. A. Heron, of the British IIusemm, kindly informs me that lirasiliensis is the name given to the southern form of lounterc, and he mentions the following chief points of difference:-in huntera there is no white in the cell of the fore wing, while in lrusilionsis there is usuatly a white patch on the discocellulars; again, in the hind wing of henteres the eye-spots are usually contluent to form a postediscal hond, while in brosiliensis the eye-spots are well separated, aml in some cases reduced to mere points. In the latter form also there is always a strongly marked discal land in both sex", which is hardly ever found in huntera males, and never in the females.

Eurema (Hypanartia) lethe, Fabr.
9. 2. 26. $2=1070$, 1071. Organ Mtus. (By the River Pacaqué.)
a. 26.8.27. $=1072$. R. Pardo to Cubatrín. (As 734.)

This specimen bears Westwood's number N. $4^{*}$.
$B z .+$ a. 28. 8. 27. $=1073$. "At Relíro." Just N. of R. Pardo.

Westwoni's list ( $\mathrm{N} .4^{*}$ ) adds another specimen, catured a. 29. 8. 27, at C'érvo. (As 527.) Against this amil the next species Westwood had written in his list the gencric name "Eurema."

Eurema (Hypanartia) bella, Fabr.
4. 11. 25. $=1074$. Ninas Geraës. (As 559.) Bz. 9. 3. 26. $=1075$. Rio de Janeiro.

This specimen bears W'estwonl's number N. 4 ; his list adds another, captured 26. 11. 26 at Santos.

These two species, originally placed under one numbor (N. 4) in a clerk's handwriting, were differentiated by Westwoot, who placed the examples of lethe under a new number: (N. $4^{*}$ ).
[To be continued.]
IV.-Notes on the Gemus Acernitom, with a Synopsis of i's Spuries and Sinlspecirs, and Descriptions of Four uene Forms. By Knud Andersen.

## The Genus Acerodon.

Type-Pteropus jubatus, Eschscholtz.
ipecirs-Six (nine reco-nizalile firma), viz. A. marliloti (three subspecies), "ilcus, celehnas, humitis, lucijor, jubatus (two subspecies).

Ronge.-Tinm group (Timor, Flores, Alor, Sumba); Celehes group (Geleles, Selayar); Talaut Islands; Philippines".

Differential characters.-Aceroron differs from Proripus by the combination of the following ilental characters: (1) Pwtwrior basal ledge of $f_{4}, m_{1}$, and $m_{2}$ extending almag inner bave of tecth as a hroed, sharply din fined shedf; this character is
 except $I^{\prime} t$, cueticune, which posesses a perfectly simiar inner basal ledge in the same tecth, but in every other respect is closely allied to the geminely. Pteropine Pt. sume ${ }^{\text {ensis }}$ : (2) a well-developed antero-internal basal cusp in $\mu^{*}$ and $m^{1}$ (a similar, but smailer, antero-internal cusp developed in

[^1]$p^{3}$ of most species and in $P_{3}$ of A. humilis, jub atus, and Tucifer) ; a corresponding cusp indicated in certain species of Pteropus, but never as well developed an I shapply ditirentiated as in Acerodon: (3) molariform teeth above and below $\left(\nu^{4}, m^{1}, p_{1}, m_{1}, m_{2}\right)$ rather shorter and broader, and main cuspis with more trenchant edges: ( $\pm$ ) $\mathrm{m}^{2}$ rather less reduced:
(5) upper incisors slenderer and more acutely pointed \%. Skull and external characters not differing. from those of Pteropus.

Originul description of genus.-Palmer $\dagger$ gives as primary relerence for the genas Acesardon, Jourdan, the "Ann. Sci. Nat., Paris, 2e sér., viii, Zool. 36")-370, Dec. 1837," and as secondary reference the "Comptes Rendus, Paris, vi, 3, 1833." To this it must be remarked, first, that these two parers give, the one exclusively, the other chiefly, E. Cuvien's "Rapport" and critical remaks on a memoir by Joardan, and that theretore, really as well as fommally, not Jourdan but F . Cuvicr is the anthor of the two papers referred $t$ o by Palmer ; second, that in both of these papers the name of the present genus occurs only in its French form (Acérolon), and therefore camot, technically, date from these papers; thim, that prime fucie it appears makely that F. C'arien's "Rispport," which was read before the Paris Acadeny, should have been published earlier in the "Annales des Sciences Naturelles' than in the 'Comptes $R$ mitus' of the meefings of the Acalemy: In these circumstances I have

[^2]had to trace tho history of Jourdan's paper and F. ''uvier's report, which appears to be as follows:-
(1) "9 Oct. $1 \times 87$ "——. R. Ac. Sci. Paris, v. pp. 5:21-524. 'This is Jourdan's original paper. It contains deseriptions of two new genera of mammals (Heteropus and Nílomys) and five new species (Heteronus allogularis, Melumus lirasiliensis,
 philipinensis). No reference to Acerodon. The paper was read before the Acalomy on!! ()ct. 1837, and presumably published very soon after.
(2) "14 Oct. 1837 "-L'Echo du Monde Savant et

 (see almese) 'This is apparently the carliest deweripion of the gemst Acoralom $\dagger$ (mon known t. Pahner). The issue of the wewly promical ' L'Echo' in which it aprated is datm! "Samedi, 14 nevelne $18: 27, "$ and was rery litely pulitiond on that day.
(3) "Nov.1837" -L'Institut, v. no. 221, p.351. Reprint of $n \mathrm{O}$. (1), suprà.
(4) "2 Jan. 1838 "-(U. R. Ac. Sci. Paris, vi. pp. 2-6.
 Lyon, ce,nceanant qualqu-s manmmems mors anx." 'This is I'almer's secondary reference. Auhhor, F. Cuvier, not Jourdan; me 'quations of Jomertan's own womk: Acorment

[^3]occurs only in the French form, "Acerodon." The mecting was held on 2 Jan. 15.3., the "Comptes Readus" presumabiy publishem a few days lator. -It apperas rather strance that ('uvin's Report on Jourdan's paper contains remasks on Acerolon, whereas Juurlan's original paper, as printed in the "Comptes Remlus" (see in). (1), sumia), has nu reference to this cemus. The explanation may le this: Cuwier's remarks on Acérodon are not very favourable for its validity as a distinct genus; as Curier, thesther wit': Dumeil, was the Academy's "Commisaire" fire zolugical fapers, he may (privat.ly) have infomel atourdum of this mpion, anl Jourdan therefore have withdrawn the description of Arerodon from the paper laid before the Acmemy, but almost simaltancomsly malishas 1 it in the "Echo" (no. (2), sum"t). But this is, of course, only conjecture.
(5) After 5 Feb. $1838-A n n$. Sci. Nat. (2) viii. Zool. pp. 367-374. A reprint of no. (土), suprà, but with the addition, in fuotnotos, of rumtations from Jonslan's orizinal paper, thes. gholatims, tak on trgether, ammunting to a conpheterphint of mu. (1). 'Ihis is J'ahner's prinary reference, evidently because this number of the 'Annales' is dated

 lished after this date.

Principul sublutivions of !mas.-The sis species of Acerodon secnenized in thispaprot tall into two manal sectiont, the one confined to the ' Timmen Celeters granpe, the other to the 'Patant and P'rilipme L-1ants. Than there frecies of the former section are more primitive, in so far as $p_{3}$ is typical L'eropin, without antero-internal basal cutp; the cars are relatively longer and the colour of the for pale above and bencaih. 'I lie two species inhabiting the Thimergroup, viz. A. mu tiluti (limur, Flowes, Alor) ami A. geleus (Simba), are clusely relaten, diffring chiefly in $-1 z^{\circ}$, whereas the
 weaker dentition. 'The the suecies of the later gonupare more specializel in having a distinct antor-ontemal basal curp in $/$; ; the ears are relatively shomer, the colurr of the fur uruch darker ; in general aspect the coluration of theses

[^4]species is much nearer to that of an ordinary Pteropus: head, back, and underparts dark, mantle paler. The single species of this group inhabiting the 'ralaut Islands (A. humilis) is easily recognizable by its small size; externally it is much like certain dark-coloured forms of P'teropus hypomelanus; the two Philippine species (A. jubatus and lucifer) are chiefly characterized by their larger size and strikingly pale-coloured nuchal patch; inter se, they differ only in size.

## Synopsis of Species and S'usppecies.

I. No antero-internal basal cusp in $p_{3}$; ears longer than muzzle (front of eye to tip of nose) ; pale-coloured forms: back and underparts approximately mars-brown or vandyckbrown, lightened with golden buffy, head and mantle essentially buffy. (Timor and Celebes groups.)
a. Dentition heavy: $m^{1}$, lengtl (antero-posterior diameter of crown) $5 \cdot 6-6 \mathrm{~mm}$. ; skull, total length $66-72 \mathrm{~mm}$. (Timor group.) $a^{1}$. Larger: skull, total length $60-72 \mathrm{~mm}$. ; forearm 139-105 mm. (Timor; Flores; Alor.)
$a^{2}$. Forearm about $139-146 \mathrm{~mm}$.
$a^{3}$. Underside of body rather thinly sprinkled with buffy hairs. (Timor.)
$b^{3}$. Underside of body thickly sprinkled with buffy hairs. (Flores.). ..... $b^{2}$. Forearm about 156 mm . (Alor.).... $b^{1}$. Smaller: skull, total length 66 mm .; forearm 135 mm . (Sumba.)
b. Dentition much weaker: $m^{1}$, length $4 \cdot \frac{5}{5}$ mm ; skull, total length $62.5-63 \mathrm{~mm}$. (Celebjes gronip.)
I1. A distinct antero-internal basal cusp in $\nu_{3}$; ears shorter than muzzle; dark-coloured forms : back and underparts seal-brown or burnt umber, more or less sprinliled with pale hairs; mantle chestnut or dark cinna-mon-rufous. (Talaut Is. ; Philippines.)
c. Small: forearm about 140 mm . no buffy nuchal patch. (Talaut Is.)

1. A mackloti.

1a. A. m. mackloti.
1b. A. m. floresii. 1c. A. m. alorensis.
2. A. giluus.
3. A. celebensis.
d. Large: forearm $165-205 \mathrm{~mm}$; a buffy nuchal patch strongly contrasting with dark mantle and sides of neck. (Philippines.)
$c^{1}$. Forearm about 165 mm . (Panay.) ... $d^{2}$. Forearm 182-205 mm. (Philippines generally.)
5. A. lucifer.
$c^{2}$. Averaging smaller: forearm 182-198 mm . (Philippines north of Mindanao.)
6. A. jubatus.

6 a. A. j. jubutus.
$d^{2}$. Averaging larger: forearm about 205 mm . (Mindanao.)

6b. 1.j. mindanemwis.

Acerodon mackloti alorensis, subsp. n.
Skull and teeth as in A.m. muckloti and floresii (skull of type, total length $71 \cdot 8 \mathrm{~mm}$. ; maxillary tooth-10w, $c-m^{2} 29 \cdot 7$; $m^{1}$, length $5 \cdot 8$, breadth $4 \cdot 5$ ), but external dimensions larger : forearm 156 mm ., against $139-146$ in nine adult specimens of the allied forms. Colour of fur scarcely differing from that of $A . m$. floresii.

Type. ô ad. (alc., skull), Alor (Ombay), Lesser Sunda Islands, April 16, 1896 ; collected by A. Everett; B.M. 98.3.11. 1.

## Acerodon gilvus, sp. n.

Skull similar to that of A. mackloti, but considerably smaller: total length (type) 66 mm ., against 69-72. Upper premolars and molars scarcely differing from those of A. mackloti, but lower incisors, $p_{1}, p_{3}, p_{1}$, and $m_{1}$, distinctly smaller. Forearm (type) $1: 35 \mathrm{~mm}$., against 139-156 in A. mackloti. Gencral style of colour as in A. mackloti, but back couspicuously paler, light cream-buffy, with the Prout'sbrown or vandyck-brown bases of the hairs perfectly concealed on back, slightly showing through on rump.

Tiple. of ad. (*kin, skull), Waingapo, Sumba, Lesser Simda lslands, Sept. 1896 ; collected by A. Everett; B.MI. 98. 11. 3. 19.

## Acerodon humilis, sp. n.

Allied to A. julutus, with which it accords in the characters of the teeth (a distinct antero-intermal basal cusp in $\gamma_{3}$ ), the size of the ears (shorter than muzzle), and general colour of the fur of the body and mantle, but much smaller, and without buffy nuchal patch. Forearm about 140 mm . Hab. Talaut Islands.

Back and rump nearly seal-brown, sprinkled all over with broccoli-brown hais, producing the general effect of a very dark shade of hair-brown. Breast, belly, and Atanks essentially like back, but pale hairs more buffy hair-brown. Mantle, sides of neck, and foreneck dark russet, slightly paler on foreneck than on nape, forming a complete collar round neck and narrowly encircling base of ears; base of hairs nearly seal-brown. Occiput, crown, interocular space, and sides of muzzle essentially similar to back; temporal region, chin, and throat blackish seal-brown, mixed with a few silvery-whitish and buffy hairs.

TYyne. of ad. (skin, skull), Lirong, Talaut Islauds, March

1897; collected by Juhn Watmetralt; prasontm liy the Hon. W. Rothschild; B.II. S. 7. 26. 6.

## Acerodon julutus, Eschsch.

Specimens a minel. - Ninetem irmo the collections of the Berlin, U.S. National, and Briti-h Masemes, viz. :-Lızom,
 Museum, nos. 340,341 , of ad., of ad., mounted, skulls
 Meym's skull ligum, l. s. at): "Philipmin-" (probably Luzon), two; Leyte, three, topotypes of Pl. auri-nuchalis; Negros, two; Dinagat, one; Mindanao, one.

Remarles.-An examination of the above material has satislied me that the P'rillppine I-hmbere inflahmel ine two races of $A$. jubatus, the one distributed over all the islands from Luzon southward to Dinagat (epecimens examined
 Mindanao. The Mindanao race differs firom typical jubatus only by its larger averagesize. There is no tangible difference in the colour of the fur of the two races. Such variations in colour as do occur (more l,lackish or more dark brownish
 umberats, hlackisi on cementate tinge of Poreneck, mome

 a-n, and lucality; pracically all col no-varimions are represented in the series of ten specimens from Luzon.
 measurements of the series of specimens.

According to the atron, the two ataes of A. jubethe whull have to stand as follows:-

## Acerodon jubatus jubatus, Eschsch.

1831. Pteropus jubatus, Eschscholtz, Zool. Atl. pt. iv. p. 1, pl. xvi. (animal, incisors, and canines) (Manila).
 xri. pt. 2, p. 604, pl. xlv. (animal), pl. xlri. figs. 1, 2, 3 (skull, teeth) (Manila).
 p. 77, pl. xii. (skull) (Leyte).

Forearm abont 152-195 mm., lower leg S6-91. Itah. Philippines, north of Mindanao.

Acerodon jubatus mindanensis, subsp. 11.
Averaging larger : forearm about 21.5 man., lower log 96. Hab. Mindanao.

V.-On a wew Cirall taken from a Diepp-sea Telegraphe Cable in the Indim Occan. By W. T. Caman, D.'sc., British Museum (Natural History).
The crab described below was presented to the British Museum, along with a number of of her rare and interesting deep-sea Crustacea, by Mr. O. G. F. Luhm, M..A., MI.B., who oltained them while acting as medical offieer on board the calle-ship. '('olonia,' of the 'Telegraph Maintenance and Construction Company. The specimens were found in repairing the cable between Adon and Zanzibar. Mot unforturately the exact locality has not leeen recoriden, but the depth is given as "about 600 fathoms."

It is must desirable that advantage should be taken of the
 Emowlatise of the deep-sea fanna. At present these opportunitios are mbstly wastel; lout a special leaflet, with instrucfions for the preservation of specimens fount on the cables, has recently heen isaned hy the Zoologieal Department of this Museum, and will le sent on application th anyome interester in the sulject. It is himpl in this way to induce some of the officers of these ships the prowne, instead of thewing overboand, the valualio materal which comes to their hamk.

## Family Xanthidæ.

## Calocarcinus *, gen. nov.

(Grapace transversely octagonal, frontonomital margin between a half and two-thimis of its greatest width; sumace smoith. Antero-lateral margin with two teeth behind onter angle of orlit. Orhits nearly comestine eyos, without fissures, completely clusen, the imer sub mbinal angle merting the front and excluiting the anteman. Antomules folding transversely. Basal semment of antema not reaching front. Eudostomial ridges extending to anterior margin of linceal frame, which is mothen on either side. Cinelipels long, massive, and unequal, the greater part of the merus extending beyond the carapace; fingers pointed. Propodus of legs having a " pulley-like " articulation with dactylus on posterior

* From ká $\lambda \omega s$, a rope or calbe, in allu-ion to the circumstances under which the specimens were captured ; if the ambiruity may be parduned, the altermative derivation from ka入̀ os, buautiful, is not inapplicable to the species.
sille. Abdomen of male with seven segments distinct, the third to fitth more firmly counected than the others.

Type species, Calocarcinus africanus, sp. n.
This genus approaches closely to Sphenomerides, Rathbun (Sphenomerus, Wood-Ma*on), though differing from it in several important characters. In having the orbital gap completely closed it agrees with the more typical Trapeziine, but in the general shape of the carapace, and especiallyoin the relative narmwness of the frontal reerion, it differs from these and from all the related sulfamilies, and assumes more the typical Xanthine aspect. On comparing the species described below with sphenomerides tropmioides, W.--IL.", and with a Trapezie, it is impossible to donbt that all three are closely related, although isphenomerides is excladed by its open orbital gap and Culocurcinus by its narrow front from eurrent definitions of the Trapezine. It is very easy to point out that the characters hitherto relied on for the subdivision of the Xanthida are all of very slight importance, but it is very difficult to suggest any better. Borradaile $\dagger$ has shown that such characters as the "pulley-like" articulation of the dactylns of the walking-legs and the clontre of the ontital gap, which might be supposel to be of systematic importance, recur in grous apparently anrelaterl, and Culocarcinus only adds to evidence already existing that the genemal proprotions of the cararea are not always trusi worthy as a guide to affinity.

## Calocarcinus africanus, sp. n.

Campace about threc-fourths as long as broal, conrex in both directions, smooth and polished, with omly slight traces of intor-requmal grooves ; octagonal in outline, the anterolateral marsins between the two pairs of antero-lateral teeth being straisht and parallel. Fro it about three-eighths of greatest whth of carapace, with a very shallow median noteh and with the supraorbital angles slightly pro lueer, hat mot acute. There is no tooth at the outer angle of the orbit. Antern-lateral margin straight to the first tonth, the distance being a litfle more than that between the first and seemed teeth, which are both blunt. Postero-lateral margin distinctly longer than antero-lateral.

Eyes smaller than in sfhenomerides, nearly concoled when retacted. Antemal flygellum as long as major

[^6]diameter of orbit. Buccal frame slightly narrowed anteriorly. Merus of third maxillipeds about as broad as long, its anterior margin straight.

Larger cheliped about two and a half times the length of the carapace; merus shaped as in Trapezic, but its front edge not expanded or serrated ; carpus with two longitudinal ridges on its outer and upper surface, somewhat rucose externally, its iumer angle forming a blunt tooth. Ifand compressed, smooth and polished except above, where it is faintly rugulose; the upper margin forms a ridge defined

Calocarcinus africanus, male, trice natural size.
externally and internally by a groove; lower edge rounded. In the larger cheliped the dopth of the palm increases slightly distally, where it is about one-half of its length and equal to the length of the fingers; in the smaller cheliped the depth does not increase, is less than half the length, and shorter than the fingers. Both fingers furrowed, slightly curved, sharp-pointed. Walking-legs moderately slender, smooth, without hairs except on the dactyli, first pair equal to or a little longer than the breadth of carapace.

Measurements in millimetres.

Ormurence. "On submarine telegraph-cable between Aden and Zanzibar, depth about 600 fathoms." One male and two ovigerous females. The eggs are minute, about $\cdot 45 \mathrm{~mm}$. in diameter.

## VI.-On Mammals from the Upper Zambezi River. By E. C. Chubb.

The Rhodesia Museum is indebted to Mr. T. N. Micklem for a collection of small mammals made by him on the Upper Zambezi River between Sesheke and the junction of the Kabompo River with the Zambezi.

It is of interest as being the first collection of properly prepared specimens f:om this region, and also in that it contains a very distinct new species of rodent-mole, which Mr. Micklem is to be congratulated upon obtaining.

The country, except for a mile or so on cither side of the Zambezi, consists of thick forests alternating with large open vleis, through the middle of which run streams flowing down into the Zambezi.

o. 12th Aug., 1908. Mambova. of. 28th Aug., 1908. Kataba River.
A bright-coloured form not unlike T. lobengulce.
"This rat lives in colonies and makes burrows, communicating with one another undergromil, in the hard ground on the edges of the forests bordering the large open vleis.
"Eaten by natives.
"Barotse name 'Peva." "-T. N. M.

## 11. Tatera neavei, Wrough.

ơ ․ . 29th Aug., 1908. Mongu.
"Barotse name 'Mtokwa.' "-T. N. M.

## 12. Saccostomus sp.

ठ. 21 st Aug., 1908. Njoko River.
ठ. 9th Sept., 1908. Nongu.
ठ. 10th Sept., 1908. Morgu.
"Feeds on seeds of trees. Trapped at night.
"Barotse name 'Situtu.'"-T. N. M.

## 13. Mus chrysophilus, de Wint.

ठ. 28th Sept., 1908. Nanziti River.
"Makes nests of grass at hottom of hollow trees."-T. N. M.

## 14. Mus sp.

$0^{\pi} 0^{\pi}$. 28th Sept., 1908. Kataba River.
Lives in holes in the swampy ground in the middle of tho large vleis, and feerls on the ronts of grass and plants.
"Barotse name 'Litundu.'"-T. N. M.

## 15. Georychus micklemi, sp. n.

of imm . 18 th Aug., 1908. Kataba River.
ס. 2ath Aug., 1908. Kataba River.
ठ . 28th Aug., 1908. Kataba River.

A black-coloured species, in this respect liffering entirely from any other members of the genus.

General colour, including limbs and tail, dark blnish black except for a large triangular patch of white on the crown, which is continued as a white dorsal stripe down to the middle of the back ; and in one example there are traces of irrecrular white markings on the nose, chin, and around the mouth. Individual hairs, both black and white, uniformly coloured for their entire length.

Skull very similar in appearance to other species of Georychus. Navals almost parailel, ending in a broad junded suture a little behind the lachrymal projection. Ascending processes of premaxillaries ending in points about 1.5 mm . Wehind the navals posteriorly, and not closing in 1owarls the midnle line. Anteonbital foramina higher than broad, almost elliptical in shape.

Dimensions of the cotypes (measured in the dry skins) :-
Head and body $170,165 \mathrm{~mm}$. ; tail 18,20 ; hind foot 24 , 23.5.

Skulls: basal length $36,32 \cdot 5$; basilar lunth :315, $28 \cdot 5$; greatest breadth $26 \cdot 5,24$ : nasals $14,125 \times 3 \cdot 5,3$; interorbital breadith $8,7.5$; intertemporal breadth $16,15 \%$; supra-auricular breadth $19,1 s$; height of anteonhital foramen $18,1 \cdot 8$; |palatilar lencth $22 \cdot 2,20$; diastema $12.8,11$; upper molar series $6.5,6.5$.

Heth. Kataba Liver, Lpper Zambezi, North-western Rhodesia.

C'otypes. Two males. Cullected by I. N. Nicklem on the 25th and 28th Aug., 1908.

Very common; I saw about a dozen, all of which were coloured similar to the three skins brought back, including the white markings. These three were dug out of the ground lyy natives. They burrow and throw up heaps of sand similar to the English mole.
"Barotse name 'Ngeti.' "-T. N. M.

## 16. Cephalophus melanorrheus, Gray.

A flat skin purchased from natives, which had been killed on the Kabompo River.
"Monkoya name 'Kashenda." "-T. N. M.

# VII.-A Revision of the Fishes of the Genus Elops. By C. 'Tate Regan, M.A. 

## Synopsis of the Species.

I. Lower jaw included, the whole of the premaxillary band uf teeth exposed when the mouth is closed.
A. 78 or 79 vertebræ; 102 to 118 scales in a longitudinal series.

12 to 15 gill-rakers on the lower part of the anterior arch

1. saurus.

18 to 20 gill-rakers on the lower part of the anterior arch
2. affinis.
B. 68 or 69 rertebre ; 94 to $9 *$ scales in a longitudinal sexies ; 12 to 15 gill-rakers on the lower part of the anterior arch.

1. Pectoral $\frac{3}{5}$ the length of head, extending a little more than $\frac{1}{2}$ of the distance from its base to the pelvics
2. senegalensis.
3. Pectoral $\frac{1}{2}$ or a little more thau $\frac{1}{2}$ the length of head, extending a little less than $\frac{1}{2}$ of the distance from its base to the pelrics.
Interorbital width 5 to $5 \frac{1}{3}$ in the length of head; length of lower jaw nearly $\frac{2}{3}$ the length of head
4. havaiensis.

Interorbital width $4 \frac{1}{2}$ in the length of head; length of lower jaw a little less than $\frac{3}{5}$ the length of head .. 5. australis.
II. Lower jaw projecting, covering the anterion part of the premaxillary band of teeth when the mouth is closed.
63 or 64 vertebre; 94 to 98 scales in a longitudinal series; 28 to 32 branchiostegals; 14 gill-rakers on the lower part of the anterior arch ................
74 vertebre ; 74 to 83 scales in a longitudinal series; 24 to 26 branchiostegals; 17 to 19 gill-rakers on the lower part of the anterior arch
6. machnata.
7. lacerta.

## 1. Elops saurus, Linn., 1766.

Argentina carolina, Linn., 176f, aud Elops inermis, Mitcl., 1815.
Depth of body nearly 6 in the length, length of head $?_{5}^{2}$ to 41. Snout as long as or longer than eye, the diameter of which is $4 \frac{1}{2}$ to 6 in the length of head; interorbital width $4 \frac{2}{3}$ to $5 \frac{1}{3}$ in the length of head. Daxillary extending beyond the eye; lower jaw included, the whole of the premaxillary band of teeth exposed when the mouth is closed; length if gular plate from less than $\frac{3}{5}$ to $\frac{2}{3}$ that of the lower jaw, which i. $\frac{5}{5}$ or a little more than $\frac{3}{5}$ of the length of head ; 25 to 36 hranchiostegals ; 12 to 15 gill-rakers on the lower part of the anterior arch. 102 to 118 scales in a longitudinal series. Dorsal $23-26$, with 18 to 20 branched rays; anal $15-16$,
with 11 or 12 branched rays; pectoral $\frac{1}{2}$ or a little more than $\frac{1}{2}$ the length of head, extending $\frac{1}{2}$ or less than $\frac{1}{2}$ of the distance from its base to the pelvies; origin of 1 lvies a little nearer to base of caudal than to end of shout. Least inpth of caudal peduncle $\frac{1}{3}$ the length of head. 78 or 79 rortente .

Atlantic coast of America from the Unitelstates to Brazil.
 total length, from W'ool's Hole, Cuba, St. Croix, and liio Janeiro.

## 2. Elops affinis, sp. n.

Differs from the precelling specios in having 15 to 20 gillrakers on the lower part of the anterior areh, lout is extremely similar to it in other respects. 79 vertebræ.

Pacific coast of Mexico, and probably from California to Ecrador.

Two specimens, $2: 30$ and 320 mm. in total length, from Mazatlan (Jordan) and Jalisco (Buller).

> 3. Elops senegalensis, sp. n.

Depth of body nearly 5 in the length, length of head 33 to 4. Snout as long as or longer than eye, the diancter of which is $4 \frac{1}{3}$ to $\overline{\frac{1}{4}}$ in the length of head; internhital winth is to $5_{3}^{\frac{1}{3}}$ in the length of heal. Maxillary extending hegonl the eye; lower jaw incenden, the whole of the pramaxillary band of tecth expmet when the mouth is elosed; lougth of sular phate $\frac{1}{2}$ to $\frac{3}{5}$ that of the lswer jatr, which is nearly ${ }^{3}$ that of the head; 80 to 23 liranchiontrgels ; 12 t, 14 gillrakers on the lower part of the anterior arch. 54 to 515 scales in a longitudinal series. Doral 2:3-26, with 17 t. 20 branched rays; anal $16-17$, with 12 or 1.3 branchod rays; pectoral :\% the lenth of head, extenling a little more than! of the clistance from its base to the pelvics; mrigin of pelvies equidistant from enl of shont and ha*e of caulal. Least depth of caudal peduncle more than $\frac{1}{3}$ the length of head. 69 vertebræ.

West Africa.
Three specimens, 170 to 320 mm . in total length, from St. Louis, Serregal (Delhez).

* The last three restebre included in my count are directed unwards. but hare distinct and so narate centra. Which, h,werea, are owrlammed by the bases of the enlaret neural spines which support the uprer caudal fin-xays, so that by some these three rertebre might lee rechoned togetimer as hypural.

## 4. Elops hawaiensis, sp. n.

D.ppth of body $5 \frac{1}{2}$ in the length, length of head $3 \frac{3}{3}$ to 4 . Sunut nearly as long as or a little longer than cye, the diameter of which is 4 to 5 in the length of head; interorbital width 5 to $5 \frac{1}{3}$ in the length of head. Maxillary extending beyond the eye; lower jaw included, the whole of the premaxillary band of teeth exposed when the mouth is clused ; length of gular plate $\frac{3}{5}$ or more than $\frac{3}{3}$ that of the lower jaw, which is $\frac{2}{3}$ or a liftle less than $\frac{2}{3}$ that of the head; 27 to 31 branchiostegals; 13 or 14 gill-rakers on the lower part of the anterior arch. 96 to 98 seales in a longitudinal serics. Dorsal 24 , with 18 branched rass; anal 15-16, with 11 or 12 branched rays; pectoral a little more than $\frac{1}{2}$ the length of head, extending a little less than $\frac{1}{2}$ of the distance from its base to the pelvics; origin of pelvics a little nearer to base of caudal than to end of suout. Least depth of caudal peduncle about $\frac{1}{3}$ the length of head. 68 vertebre.

Hawaii.
T'wo specimens, 220 and 400 mm . in total length.
This species is very close to E. senegal-nsis, but has the eye a little larger, paired fins shorter, \&c.

## 5. Elops australis, sp. n.

Depth of boly 5 in the length, length of heal 41. Snout a little longer than eye, the diameter of which is ") in the longth of head; interorbital width $4 \frac{1}{2}$ in the length of heand. Masillary extending beyond the eye; lower jaw includel, the promaxillary band of teeth exposed when the mouth is closed; length of gular plate a litile less than $\frac{3}{5}$ that of the lower jaw, which is a little less than $\frac{3}{3}$ the length of head ; 31 branchiostegrals; 13 gill-rakers on the lower part of the anterior arch. 95 scales in a longitudinal series. Dorshly, with 18 branched rays; anal 15 , with 11 branched rays; pectoral slightly more than $\frac{1}{2}$ the length of head, extending a little less than $\frac{1}{2}$ of the distance from its base to the pelvics; origin of pelvics equidistant from end of sumat and base of caudal. Least depth of caudal peduncle nearly $\frac{2}{5}$ the lengeth of head. 69 vertebræ.

New South Wales.
A single specimen, 330 mm . in total length, from Port Jackson.

## 6. Elops machnata, Forsk., 1775.

Elops capensis, Smith, 1845, aud Elops purpurascens, Richards., 18.16.
Depth of body 5 to $5 \frac{2}{3}$ in the length, length of head $4 \frac{1}{3}$ to

4\%. Snout as long as or longer than eyn, the diameter of which is $4 \frac{2}{5}$ to $5 \frac{1}{2}$ in the length of hearl; interonhital width $4 \frac{1}{2}$ to $4 \frac{2}{5}$ in the length of head. Maxillery extending berond the eye; lower jaw projecting, covering the anterior part of the premaxillary band of teeth when the mouth is closed; gular plate $\frac{3}{5}$ or a little less than $\frac{3}{3}$ the longth of the lower jaw, which is more than $\frac{8}{5}$ that of the head ; 28 to 32 branchiostegals ; 14 gill-rakers on the lower part of the anturior arch. 94 to 98 scales in a longitudimal series. Donsal $21-23$, with 16 or 17 branched rays; anal 15-16, with 11 or 12 branched rays; pectoral $\frac{3}{5}$ the length of head, extending a little less than $\frac{1}{2}$ of the distance from its base to the pelvics ; origin of pelvics a little nearer to base of candal than to chel of smont. Least depth of caudal peduncle $\frac{1}{5}$ to $\frac{1}{3}$ the length of head. 63 or 64 vertebræ.

From the Cape of Groorl Hope to China and Japan.
Here described from a Madras specimen of 3.59 mm . and one from the Cape measuring 680 mm . in total length. The latter is a more slender fish than the fomer, but seem- to bee the same species. Comnts of scalce, fin-rays, de. in two smatl specimens ( 110 mm .) from Matras, and of stuffin examples from South Africa and China, are include $\mid$ in the description. 'T'wo skins from Dr. Kirk's collection, labelled reapectively Lake Ňyasa and Shiré River, may belong to this species.

## 7. Elops lacerta, Cuv. \& Val., 1846.

Elops congicus, Bouleng., 1898.
This small species, reaching a length of 560 mm . in WestAfrican rivers, agrees with the preceding in the structure of the mouth, but has fewer branchiostegals, more numerous gill-rakers, larger scalcs, vertebre in greater number, \&c.

## VIII.-Descriptions oi Turo nem Species on Rilunchota from <br> Bengal. By W. L. Distant.

## Heteroptera.

Fam. Saldidæ.

## Subfam. Saldinte.

## Valleriola cicindeloides, sp. n.

Greyish ochraceous, thickly shortly palely pilose; head, anterior lobe of pronotum, and four short longitudinal fascize
(not reaching basal margin and sometimes fused in pairs) to posterior lobe greyish fuscous; eyes, ocelli, anterior collar to pronotum, and a small spot near each posterior pronotal angle piceous; scutellum greyish fuscous, with the apex pale; body beneath and legs greyish ochraceous; longitudinal streaks and apices to femora and transverse segmental shadings to abdomen beneath piceous; corium greyish fuscous, costal and imer claval margins, two spots on clavus (one near base, the other near apex), two spots near middle of corimm, and a cluster of spots at its apes very pale ochraceous; membrane pale greyisin ochraceous, the veins fuscous; antema pale fuscous, basal joint and apex of apical joint very pale ochraccous, second joint ochraceons, with its apex darker; head transversely concave between the eyes; pronotum strongly transversely impressed behind the dark anterior collar, the anterior lobe with the anterior and lateral margins and a central longitudinal line greyish ochraceous, its surface with some large and coarse punctures, posterior lobe subgranulose, giving the appearance of clense paler spots, the lateral margins longly pilose; scutellum foveately depressed on basal area, its apical area ridged; legs finely pilose, the femora more strongly so ; ocelli two.

Length $5 \frac{1}{2} \mathrm{~mm}$.
Hab. Bengal ; Pusa (Maxwell-Lefroy).

## Homoptera.

## Fam. Fulgoridæ.

Subfam. Isstac.

## Hilda bengalensis, sp. n .

Vertex, pronotum, and scutellum pale orreen, extreme apical margin of vertex almost continuonsly black; pronotum with the margins testaceous; basal area of face between the eyes black, with four prominent small white spots, in some specimens the spots near the eyes are obsolete and only the two central spots are visible, this black area margined posteriorly with greyish white ; clypeus, body beneath, and legs ochraceous; tegmina pale testaceous, basal half of clavus castaneous, with an apical white margin and this dark area outwardly continued on corium, with a large whitish spot varying in size and shape, corium also crossed beyond middle by a whitish transverse fascia narrowly margined with black and broadly angulated on each side at costal margin, apical area a little paler in hue and inwardly defined and margined by a
waved pale greyish line, and preceded near suture by a dark spot comtaning one or more small pupillate white spots; wings hyaline ; face stomgly transwersly impersed butween the insertions of the antema, medially anculate, the lateral margins bufore the anculation monlorately concave; vertex with a distinct longitudinal impression.

Vars.-Becoming darker in hue, the pale green colonation mplaced by dak tretaccons, and with a laree picoms on dusky sport in the white subhasal spot to corium and in the postmedial transverse whitish fascia to same.

Long., incl. tegm., $5-5 \frac{1}{2} \mathrm{~mm}$.
Hab. Bengal; Pusa, Muzaffarpur, Barisal.
Allied to II. maleycusis, Dist., from which it diffors hey the longitulitally impressel vertes, the amghate fare, conis lrous lews. pratial or complete abmence of the collate spits on:

 in my conclu-ion of the Appoliz ti, the Rinyn-ly ind fontion of the 'F'auna of British India.'

##  the Niger. By G. A. Boulenger, F.R.S.

## Eleotris pleurops.

Tondy rahnor strongly compresseal, its depth 3 times in total loneth: lometh of head $3 \frac{1}{2}$ times in total length. Ilmad as
 shout broal, truncate, as long as eye; eye permoty latral, 4 times in length of head and twice in intormbital width; lower jaw not projecting ; masillary not quite reaching on below anterion horder of eye ; min canne teeth: the mepercular spine. Dorsals VİI, I 8, well separated from each whem, longest hays $\frac{2}{5}$ length of head. Anal 110 , opmesto to socond comsal. Pocional $\frac{4}{5}$ lemgth of head, vemtrat \%. Couda! rourded-subacuminate, as long as heand. Candal peduncle $1 \frac{1}{2}$ times as long as deepp. Scales stromsty ciliateri, 32 in a longitudinal series, 10 hetween urigin of dumal ami amal. Hark brown, lighter on the belly; fins brown, ilomals with round whitish spots.

Total length 75 mm .
A single specimen from the Lower Nifrr, presented th the British Duscum loy Mr. J. Paul Amold, of Hanburg.

## Previols History of "Eocidarts," and Sblectime of Genotype.

## In my note on "Echinocrinus versus Archerocideris" "

[^7](Nor. 1907) allusion was made to Eocilaris. This is a generic name that has been variously interpreted, and some decision concerning it and other names involved had to be come to for my memoir on "The Triassic Echinoderms of" Bakony" (in the press). After pages 84-88 containing my conclusions had been passed for press, I learned from Professor R. T. Jackson's letters that he had come to a different conclusion concerning Eocidaris, and I now find his view supported by Professor H. Lyman (Hark in his valuable synopsis of "The Cidaridæ" (Dec. 1907).

Professor Jackson and I agree that "Eocidaris" is a muisance, and we should be only too glad to get it decently out of the way. The process of sepulture adopted by Professors Jackson and Clark is to take Cidaris Reyserlingi (ieinitz as genotype, and in consequence to regard Eocidaris as a synonym of Cidaris. This seems to me to be rather a mock funeral. Granting for the moment that (i. Reyserlingi might be the true Eocidaris, then, in the first place, one would want to be quite certain as to the meaning of "Cidaris," a question to which every recent authority gives a different answer (Bather, March \& July, 1908) ; secondly, I should deny that C. keyserlingi was a Cidaris, even as that genns is interpreted by Professor Clark, and I should feel obliged to retain the name Locidaris for a genus butter known by at least one other name, namely Miocidaris.

But I did not feel bound to take Cidaris keysertingi as genotype of Eocidaris ; on the contrary, simple adherence to
adrocate the use of Echinocrinus. Not so: I have merely pointed out that all accepted rules compel such use. Were there any tribunal before which this question might be laid as an open one, $I$ should plead for the absolute rejection of Ěhinocrinus. If the Committee on Nomenclature appointed by the International Concress of Zoulogists is to be constituted such a tribunal, I hope that Dr. Gregorr, Dr. Jackson, and others will join me in sulmitting this case for ite decision. I am ready to accept its decision. Is Dr. Gregory likewise ready?

Unless zoologists wish to go on wasting their time in futile squabbling orer these dreary questions of nomenclature, they must adhere rigidly to the rules drawn up by the only existing body that can be considered at all representative; or, in cases of doubt and obrious grave inconrenience, they must accept as final the ruling of that same body. In these debatable matters there is no other method of applying "common sense"; the altermative is independent julgment, and from that we have suffered too long already.
P.S.-This fontnote was written some months hefore sereral British zoologists raised the reneral question in ' 'Nature' (p. $394 ; 27$ Aur., 1:0)*) and at the Dublin Meeting of the British Association (see "Nature, p. 1547; :20 Oct., 1908). With their pretest I agree, so far as I understand it; but I do not understand what practical result- are expected from the resolution that was passed.
the rules of momenclature, without recarl to ulterior consoquences, seemed to have reduced Viociluris to two species an chscure that no one was likely ever to learn more ab, ut them. Thus Eocidaris wat, one hopel, quietly laid on the shelf.

It now seems advisable to defend in greater detail the conclusions set forth in my memoir with a brevity that might have been praiseworthy had everyme been prepared to accept them.

Deson' (1856, 'Sympsis,' P. 155) based the grous Eocitheris on interambulacral plates and radioles. "Ces plaques étant hexagonales, elles doivent par eom-éduent rentrer dans la tribu des Teserelles. Un eros tuborenle par plaque. (is tubereule est à base lise of perforé ans,mmet, main il eliffere de ceux du genre Aechmomiluris mar l'ahsence d'un second someau. Ambulacos incombi- limliohes getes, garnis de pretites épines sporadignes." It is clear from this that, mot only was Limeduris definet as one of the Tersellati, but that it betonged th the Family now called Arehenceitanide on Lepidecidarida. In shome, the generic concept was precisely That which has subsernomly given rime io Cidarotrous (ste Bather, Nov. 1907).

To Eucidaris Desur referred six species, in an order govemed ly their stratigraphical position, the newest coming first :-

| [Cidaris] kaiserlingii [sic] Geinitz. | Lower Zeclstein. |

| Palochimus vernexillanus King. | Permian. |
| Cidaris rossica Buch. | Carboniferous. |
| Echinocrinus munsterianus Koninck, M'Coy. | Carboniferous. |
| Cidaris lecispinana Sandberger. | Deronian. |
| Cidaris scrobiculata Sandberger. | Devonian. |

Of these species ('. mision was inclulen with doubt, since Desor was not certain that the plate was hexagonal. E. munsteriamus was placed here only on the don:tful evidence of a radiole. It therefore fullows that the genotype, whenarer selected, must the one of the ather fiour species.

We have now to see what action has been taken by subsequent authors.
II. B. Geinitz (1S61, P, 108) accepted Desor's reference of Ciduris lieyserlinut to Eociduris, and said that the interambulacrals were "sehr deutlich sechsseitig," but his figmes (Taf. xx. figs. 7, 8, 3) show phates that are obvionsly fivesided. The same anthor ( $1566, \mathrm{p} .61$ ), describing a new species, Eocidaris hullimus, did not discnss the genus in any way.
J. Hall (1867-i0, 1, 341) referred İchinus diydenensis

Vamusem to Eociduris, and based on that species a more rivtiled diagnosis of the genus. He did not discuss the European species of Eocidaris.

Qucnsterlt (1872-5, p. 162) compared Palcochinus vernenilicena [sic] King with his own ('iluris coceves [sic], but did not regard them as Eocilaris. He mentioned Desor's reference of Cidaris keyserlingi Geinitz to Eocidaris, but printed out that the later figures showed the species to have interambulacra of true Cidail type. On p. 374 he alluded 1o D esor's reference of C'detris rossicu to Encidturis because of its lack of a basal terrace, but preferred with Trautschold to leave it in Archencideris. ( $=$ Echinocrimus). "According to this criterion," he said, apparently with a touch of sarcasm, "the little remains of Cillaris leverspina and C' scrobiculata should belong to Eocidaris." These at any rate are the only species that Quenstelt left in Eocildaris in so far as he accepted the genus at all.
S. Loven ( $1 \times 7.5, ~ p .42$ ) gave a diagnosis based on Desor, and included the following specties in order: E. leysertingi, E. verneuiliunu, E. scrubiculata, E. Tincispina, E. diydenensis. He placed the doubtful C. rossice anl C. munsteriona in Archeocideris. Otherwise his remarts are not so helpful as those of Quenstedt.
A. Pomel (1883, p. 113) says that Eocilaris "Ne parait difiérer d'Avcheocilario que par ses tubercnles, dont la base mausue de la crête concentrique au cercle scr biculaire." lle thinks it may include the radioles known as Tenociduris, and mentions the following species in order : E. lieyserlingi, E. vermeuiliuna, E. scrobiculuta, E. drydenensis. It is clear that Pomel was accuainted neither with the fossils themselves nor with the remarks of Quenstedt.

The latter, at any rate, were known to W. Waagen (1885), p. 818), who, however, crroncously says "Quenstedt admits only the carboniferous species in the genns Eociduris." Waagen probalily meant that Quenstedt removed from Euciduris the Permian and possible Triassic species. Waagen himself makes the curious and untenable suguestion that C. grendereu Geldt. has hexagonal interambulacral plates figured by Quenstedt, and had better be transferred to E'ocidaris. In Ciduris forbesiuna Kon:, which he here refers to Eucidaris, Waagen deacribes "a derply crenulated collar" round the mamelon, and in comparing this species with Eociduris rossice he twice insists that the alssence of crenclation in that species is only apparent, and due to weathering. Why Waagen, in opposition to Desor's clear statement, should have thought crenclation a character of Eocideris is nowhere explained.

Down to this point it is perfectly plain that Eociduris was miversally regarded as a Palechinoid or Tessellate, with hexagonal interambulacrals of L pidecidaroid type, differinf from those of Echinocrinus (or Archoocithris) in the alsence of a basal terrace. It had further been prointe 1 out by Quenstedt that Ciduris keyserlingi and C. verneuiliuna, not to mention C. coreca, could not be placed in Eocidaris because they were Cidaride and not Palechinoids. The two species C. rossice and C. mumsteriana, in addition to having been doubtful from the begiming, were now generally referred to Echinocrimus. There remained then available for the type of Eucilewis only the two Ihe vonian species C. levispine and (. scrobiculutu. The varions American species, notably İ. drydenensis, though often utilised for the interpretation of the genns, never had any claim to be regarded as genosyntypes.

This clear and, from the nomenclatoral standpoint, satisfactory state of affairs was all of a sulden complicated by the irruption of an enthusiastic student of recent seaurchins. In giving a summary of various Cidaride with flexible test, L. Doederlein ( 1557, p. 39) comrectly turned his attention to C'iduris keyserlingi Geinitz, and, leing desirons of keeping this in a genus distinct from the recent Ciluris, he retaned for it the name Eocillaris given to it by Desor and accopted by (iemitz at a time when its true structure was not realisen. Dr. Doederlein himself gave a more detailed and mose correct deseription of an interambulacrum of the species from the Zechstein of I 'üssneck, and, in conseguence of the facts thus clicited by him, he drew up the following diagnosis of Eociluris:-" Paleozoische (idariden von geringer (Griosse, mit schneidendem ambulacralen liand des I[nter] A [mbulacral] F[eld]. Coronalplatten in geringer Anzahl ; Hauptwarzen klein, gekentt; Warzenhafe elliptisch, etwas vertieft, zusammenfliessend: Ncrobicularring nicht auffallend. Arten: Keyserlineni aus dem Zechstein u. a." Note the plural, " und andere."

Into the details of Doederlein's account, more than confirmed in the contemporary description by Kolesch (June 1887), we need not enter for the present. Sufficient to note that both these accurate observers fullowed Quenstedt in maintaining the truly Cidarid nature of the species before them. The questions that now concern us are : first, did Doederlein intend to fix on C. keyserlingi as the genotype? Secondly, had he the right so to do? Both these questions I answer in the negative. As for the first, there is no reason to suppose any such thing, since Doederlein fixed on
no genotype for any of the other genera, whether new or old, discussed by him. He mentioned E. Reyser?ingi by name hecause it was the form next to his hanrl, and it was not his purpose to investigate all the other species of the genus; or, to look at the matter from the other side, he used the name Eociluris for his new generic concept merely because he found the name already in use *. But, even assuming that he did mean to fis on C. Aeyserlingi as the genotype of Eociduris Desor, I maintain that he was prevented by the prior action of Quenstedt, who had scized on the essential point and removed C. keyserlingi from Eocidaris.

In coming to this conclusinn, I am glad to find myself essentially in accord with Dr. A. Tornquist, who, since he too hailed from Strasshurg University, was doubtless familiar with the views of his colleague. In $18: 6(p .38)$ he discussed the validity of Eocidaris, and once again pointed out that C. Reyserlinui was a true Cidarid. But to interpret Eucidaris by C. lieyserlingi, and toplace it in the Cidarilse, as Zittel had done (1895, p. 186), was, he maintane f, far from Desor's intention. Eocidaris must remain in the Archæocidaridæ; that there really did exist forms corresponding to the diagnosis of Desor, had been proved by the American Eociduris drydenensis and Lemidoriduris squamosa, while European representatives were $\mathscr{L}$ ciduris scrubiculata and İ. verneuiliana. As for Ciduris rossicn, though sume of its interambulacrals, notably in the adambulacral colurnis, were devoid of a basal terace, and therefore of E cilaris type as Desor supposed, others hal that structure and therefore justified the refurence of the species to Archersilaris (=Echinocrinus). Both here and in a later paper (1897, p. $48=770$ ), Dr. Tomquist showed a strong inclination to interpret Eucicuris in: the light of E: chiydenensis. But this species, being miknown to Desor, could not be taken as genotype. Essentially, then, 'Tomquist confirmed Quenstedt, by transferring ('. rossica and hy eliminating C. keysorlingi: "Huir diese ist allenfanls cine nene Gattung aufzustellen, wenn man sie nicht mit Cidaris vereinigen will."

So far as Euciduris was concerned, the same position was taken up by that very learned writer on fossil Echinoids, Mr. J. Lambert ( $1900, \mathrm{p}$. $\mathrm{B}_{\mathrm{o}}$ ). IHaving pointed out that E. Teyserlingi, E. verneriliana, and E. rossica did not agree in essential points with Desor's diagnosis, he referred them

* The International Cole of Zoolorical Nomenclatur. (1s(0) sars under Article 30, rule $g$ : "The meaning of the expression 'select a type' is to be rigidly construed. Mention of a sperife a an illnatration or example of a genus does not constitute a selection of a type."

Ann. \& May. N. Hist. Ser. 8. Vol. iii.
respectively to Eotiaris n. g., Permocilaris n. g., an 1 Archuociduris sens. restr. 'The last of these was disensse l in my previous paper (Nov. 1907) ; to the other two we shall recur. Here it need only be noted that the result of Lambert's action, as of Qunstelt's, was to leave in Eocidaris only two of the original species-E. leveispina and E. scrobiculata.

I conclude, then, in opposition to Professors Jackson and Clark, that we are bound by the actions of Quenstedt, 'Tornquist, and Lambert to regard liciduris as restricted, partly by elimination, partly by definite statement, to the two Devonian species of Santherger*. 'To prevent further confusion it is neceseary to fis on ome of these as genutyp, and, in making a chonce, regarl whuld be hat to the fact that in I'. lervisping the radinle has been desuribed as well as the interambulacrals. Therefine I decide on that species, and to avoid all other sourees of confusion I indicate as its type (lecto-holotype) the original of Sanlberger's pl. xxxv. fig. $2 a$, which figure corresponds most closely with Sandberger's own description (1855, p. 382).

Whether this conclusion is fortunate or unfortunate we need mot stop, to decide, since that can have no bearing on its correctness. At any rate, as will appear in the sequel, it disproses of the name Eocidaris more effectually than the action of Prufisans Clank and Jackson; therefore they, at least, should be satisfied.

## Eocidarts levtispina and E. scrobiculata.

It would be of more int rest to discuas the validity and systematic pusition of Eucideris as thus interpreted, and here it is indeed untomate that the materials for a decision are so scanty. A few remarks may, however, be ventured on Sandberger's specimens, which were very kintly lent to me in January, 190x, by the Natural History Museum of the town of Wiestaden. My thanks are due to GehemerSanitïtsrath Dr. Arnold l'agenstecher and to Dr. L. Lampe for leaving the specimens in my hands so long.

The specimens, which come from the Middle Deronian Stringocephalus Limestone of Tillmar, are all much broken, with surfaces we thered and decorticated, and with the natural margins of the plates destroyed.
'Taking the first genotype, Eorilaris levinpina, we turn to the lecto-holutype, the original of Sandberger's fig. 2 a

[^8](our Pl. I. fig. 1). This is an interambulacral plate, with mamelon elongate, probably in a meridian direction, perforate, the perforation similarly elongate, rising from a slight platform, now almost entirely broken away and retaining no trace of a parapet if ever there was one. The boss passes with a gentle convexo-concave slope, and no trace of a basal terrace, into the slightly depressed area, which is bounded by no distinct rim. There appears to have been a complete circle, perhaps a trifle flattened above and below, of scrobicular tubercles. Those on one side, to the number of four, were larger than the others, were donbtless mamelonate, and though much worn still show faint traces of scrobiculation; they may be called secondary tubercles. Those on the other side were much smaller, more numerous, numbering 8 or 9 , and rather irregular in position; they may be called tertiary tubercles. Their mamelons, still clearly preserved in some cases, were almost certainly imperforate, as stated by Simuberger, and in no way justify Desor's sugrestion of pertoration, which was doubtless based on some obscure marking in Sandberger's figure. The tertiary tubercles can be traced across one end of the scrobicule (the left in our figure), and
$$
\text { Fig. } 1 .
$$

Restored diagram of holotype of Eocidaris levispina, enlarged $2 \frac{1}{4}$ diameters.
there is some indication that they formed a similar line at the other end, but that margin is more broken away. The extrascrobieular tract adjoining the lateral tertiary tubercles slopes sharply downwards, and bears three elevations (there may have been a fourth, to the right in our figure). These elevations do not appear to be the remains of tubercles, but seem rather to represent a folding or denticulation of that margin of the plate. This suggests that the margin in question is adambulacral, a view consonant with the position of the larger (secondary) tubercles on the opposite side of the scrobicule. Un this evidence we may, perhaps, venture to reconstruct the plate as shown in the amexed diagram (text-fig. 1).

The original of Sandberges's fig. 26 (our Pl. I. fič. 2 ) is
a fragment, preserving only the mamelon, part of the bros, and faint traces of about lialf the scrobicular ring of tubercles, all apparently teitiary; there is uo trace of any secondary tuh) rele. Since this agrees with the lecto-holutype in all those characters that are preserved, it may well h, long to the same species; and, if so, it indicates that the platiorm roumd the mamelon was slightly hollowed, or, in other words, had a slight parapet ; the mamelom it- 1 if is much depressed, and has a very short neck, which is not undercut.

The original of Sandloerger's fig. 2 (our Pl. I. fig. 3) is too numh broken and wom to afford any safe evidence. It may lelong to the same sureies, and at any rate presents no features inconsistent with the precoding account. There is amother imperfect plate, mufiguret, of much the same character.
'The original of sandberger's fiz $22 d$ is the posimal end of a primary radiole (our I'l. 1. fig. 4). The evilence on which this is referred to the same species as the three interambulacral plates is memely the nocurrence of this and similar fragmonts in the same stratum as those platos, ami the General conre-pmbence in size between it- a e tabulum and the juinay tubereles of the plates. The shat is subcylindrical and smouth, but the sathate septa of its mierostructure ame just viable on the sumfer as fine lomgitulinal stria. Its diameters are 3.9 mm . and 3.3 mm . Tisere is sun trace of an axial lumen. Do collesette can be heroted. The anmus sweds cut gently to diametne of 4.5 ami 3.7 mm ., chil pates with a slight concave curve into the g-ntly monlal base. The acetabular margin is a smonth raine frim, much wom in the spocimen, with sutnill diameters of 3.9 mm . aml $2 \cdot 1 \mathrm{~mm}$. Dince the hase has been crackel amd is traversed by a vein of calcite, the lonere diameters of ammber and acetablum should be taken as about 5 mm . shorter than the mea-urements given.

The orginal of Sandluerger's fig. $2 c$ is the proximal partion of a radiole, 14.6 mm . long. It is attadhed to a fragment of ciy-talline limestone, and its outer layers are stained, like minat of the limeston.., a ligit pinkish red. A!l the nther specimens are of a dull grey colour. In this radiole the shaft appears to have been revatively thimer than in the original of tig. $2 d$, bing 2.7 mm . in both directions at the distal end, and to have taperei more towands the pmamal end, where it has a diancter of $2 \cdot 3 \mathrm{~mm}$, and then expands again towards the annulus. The base is of the same general claracter as in fic. ? / . The chief difforence lies in thaces of a longitudinal raging, exceedingly oiscure, but apparently
quite different from the smooth surface of fig. $2(\boldsymbol{l}$. The longitudinal striation due to the microstructure is seen on the ridges and in the spaces between them. The number of ridges to be detected on one side of the shaft is 13 or 14 ; but I am unable to see that they occur on the other side of the shaft. The difference in form of the shaft, the different matrix, and the suggestion, obscure thongh it be, of a different ormament, render it probable that this radiole does not belong to the same suecies as the other radiole ; and, if either be conspecific with the lecto-holotype of Cidaris hevispina, it is more likely to be the original of Sandberger's fig. $2 d$. 'Two other fragments, unfigured, are of the same nature as the latter specimen, and show that the radiole was slightly fusiform, smooth, and finely striate throughout.

Miss Mary Klem (1:04, p. 69) gives as the sole deseription of this species: "Primary spines cylindrical and ornamented with about twenty-three longitudinal ribs. These ribs are muricated oppositely." This information is not given by any of the authors quoted by Miss Klem, and she does not say that she has herself examined any spocimens. Of the two radioles figured by Sandberger, that which probably belongs to the species is neither cylindrical nor ribbed; the other one may possibly have been ribbed, but there is no evidence that its ribs were muricate.
'Ihe holotype of Ciduris scrobiculata Sandberger (their fis. 3, our Pl. I. fig. 5) is an interambulacral plate of abont the same area as the lectotype of (O. levispina, but apparently less thick and with a less prominent boss. The mamelon, platform, boss, and scrobicule are of the same general character as in C . leveispinct but the manelon is not so much extended, the scrobicular ring is circular, its tubercles, which show faint traces of scrobiculation, are intermediate in size between the secondaries and tertiaries of $C$. leveispina, and appear to have been more regular and more equally spaced. The extra-scrobicular surface was probably smooth.

The Sandbergers may have been right in regarding this specimen as of a different species; but if one were to maintain that it came merely from a different part of the test of C. levispina, I do not see how that could be disproved. There certainly scems no reason for Desor's suggestion that it may belong to a different genus.
'llie systematic position of these two species is doubtful. Since the outlines are not preserved in any of the plates, the only evidence that they belong to a genus with more than two columns of interambulacrals to an area is the it priori evidence afforded by their antiquity. 'Ihis, however, must be accepted in the absence of proof to the contrary.

The feature seized on by Desor, the absence of a basal terrace, is not enough to distinguish these species from Echinocrinus ( = Archicocidaris), especially when so few plates are known. Still the general nature of the ornament, at least in C. levispina, and more particularly the character of the radioles, are enough to warrant the separation. The radiole of $C$. lavispinar rather resembles those of Lepidocidur is squamosa, as I judge from excellent photorraphs kindly lent me by Professor Jackson, but that species has slight extrascrobicular ornament. Without knowlenge of larger portions of the test, it would be quite unsate to refer C"illaris lervispina to either Echinocrinus or Lepideciduris; lut there seems no reason why it should not remain in the Lepidocidaride, as genotype of a distinct genus, Eocidaris Desor.

## Carbuniferues Specifs meferred tu Liocidarts.

The discussion of the American species at one time on another refered to Jocidaris may safely he left to Professon Jackson, who will, one hopes, at last provide a figure of the much-discussed $E:$ diydenensis. The others are $E:$ D D/uini
 (1866).

Neither does it seem necessary to say nore about Focidaris rossica and $I:$. munsteriana, which have been dealt with by Tornquist, Ilesse, and others, and will receive further attention from Jackson. Both donbtless belong to Echinocrinus.

## Permian Species referred to Eocidaris.

For detailed information regarding $C$. $k$ eyserlingi we are indebted mainly to K. Kolesch (1887), but also to Doerlerlein (1887), E. Spandel ( 1898 , pp. $33-37$, pl. xiii. ff. $1-6$ ), and E. K. Hesse (1900, pp. 213, 214). (ruml specimens from Püssneck in the British Musenm (E 1119, E1121) have enabled me to check several of the statements made by these authors.

In supposing the shape to be that of an ordinary Cidaris or Inemiciduris, Spandel seems to be more correct than Kolesch, who perhaps forgot to leave enongh room for the apical system.

In assigning to a single interambulacral column six full plates, Spandel is probably nearer the truth than Kolesch with his seven plates, and certainly nearer than Doederlein with his four or five.

Spandel, however, seems to think that there was at the
adoral end of each interambulacrum " ein Halbtäfelchen, wodurch die paarigen Interambulacralreihen, in welchen die Assch alternieren, gegen das Peristom beglichen werden." It must not be inferred from this that there was any relic of the primitive median single interambulacral ; the plate in question is merely the adoral plate of either the $a$ or $b$ column in process of resorption. This, if reckoned in, gives 7 plates to the column in which it lies.

Doederlein, Kolesch, and Spandel agree with Qienstedtin describing the interambulacral plates as five-sided. It is only the extreme adoral or adapical plates that may be four-sided in consequence of resorption or incomplete growth respectively. As regards the normal interambulacrals, Spandel is right in describing the adoral margin as convex, the adapical as concave ; but this is not always obvious, nor is the curve very regular.

Duederlein noticed that the adambulacral margin was sharply bevelled underneath, "schneidend"; but it was left for spandel to observe the denticles on the bevel (see his pl. xiii. f. 4 b). This is confirmed by Brit. Mus. E 1121 (Pl. I. fig. 6), which further shows that the regular denticulation seen in Spandel's figure is characteristic of the ambital interambulacrals. Nearer the peristome the bevel forms a less acute angle and the denticulation is less regular. This agrees with what may be observed in allied species; but for a full discussion of these interesting structures I must refer to my memoir on the Bakony fossils. The same specimen shows that there are about four denticles to each ambital interambulacral (as figured by Spandel), whence it may be inferred that there were also about fou ambulacrals to the interambulacral. Kolesch, arguing from the external view of the margin, likewise inferred that $3-1$ ambulacrals went 10 a small interambulacral, 5-6 to the largest ones. The denticles are not quite at right angles to the adradial margin, as might be inferred from Spandel's figure, but slope slightly adradially and adorally, and from this it follows that the ambulacrals lay at a corresponding angle.

In the 'Triassic Echinoderms of Bakony' the structure of the sutures between the interambulacral plates in this and allied species is discussed at some length, and my inability to follow spandel's account is there explained. Here it will be enough to give the conclusions based on an independent examination of the British Muscum specimens as interpreted in the light of the Lepidocidaridæ.

| Margin | ndiadial. | adapical. | andoral. | apiendinterradial. | arudinterradial. |
| :---: | :---: | :---: | :---: | :---: | :---: |
| Beyel facing | inwards. | inwards. | outwards. | inwards. | outwards. |
| Nature of SUTURE: | transverse denticles. | ridge on inner margin, sometimes. | ridge on outer margin, usually. | smooth. | smonth. |

Acerding to fipandel, the ridge serves as a stop ("WilerJager ") fire the adjoining plate; lut his view is inconsistent with the existence of a ringe on hoth uphr and lower margins. There is more probahility in the opinion expressed ly 'lomquist ( 1896 ), in reference to a similar structure in lechinocrimus, that the ridge merely marks a $n$ ouve for the attachment of the miting ligament. On this view, the presence of a rilge would indicate greater rather than luss flexilility. The interambulacrals of (iiduris lingserlingi must, hiwerer, have been united somewhat firmly, since lange pertions of ambulacra are more common than ioolated ambulacrals, and, except on the adrarlial marpins, they are bomded ly fractures rather than hy sutural surfaces.

The same fragment (E 1121) that shows the denticulation sop lainly also bears wituess to comsiderable thickeniner of the interanlulacrun towads the peristome and to the xistence of an internal prominence on each side of the interamblacrum, for the attachment of the jaw-museles. It is curions that 1.0 remains of the jaw-apharatue, which this species certainly fossessed, have yet l, en recurded.

In reference to the structure of the main tubercle, Kolesch criticises Geinitz and is in turn eriticised by Spandel. Brictly put, the manelon is perforate, depressed hemispherical, with slightly undercut neck, supported on a flush platform of nearly twice the diameter of the neck, having well-marked crencllae, of which the mmbore rises to thirteen in the larger ambital plates; from this the boss slope: with slightly concave curve to the depressed definite scrobicule, and, while generaliy smooth, is occasionally marked by slight folds apparently continums with the crenellas. The scrobicule is not so much a transverse ellipse as a circle, which is truncate above and below where contiguous or, as in younger individuals and hates, confluent with the adjacent scrobicules. There is no definite ring of scrobicular tubercles, but the extra-scrobicular surface is covered with close-set,
imperforate, rounded eminences, varying in size, and the larger of them apparently mamelonate (i. e. tubereles). From 5 to 7 of them border one side of a larger sembicale, and the same number its other sile. The larger serobicales are usually separated by a single line of about 3 to 5 miliaries (or possibly tubercles).

As regards the radioles, I have nothing to add to the accounts of Kolesch, spandel, and Iesse (Pl. I. fig. 7).

Inst of the writers who have dealt with Ciduris keyserlingi have discussed its relations to C. verneutilunce (King). While Kine, Geinitz, and Spandel have regrarded them as a single species, Desor and Kolesch have separated them, though admitting their clove relationship; but it has been reserved for Lambert ( $1899,190(1)$ to place them in two distinct genera-Eotiaris and Permocidaris.

How far any of these writers have based remarks on a study of actual specimens of the two species, they have not told us. The following remarks are based on the specimens of C'ilderis keyserlingi in the British Museum, which have just been described, and on a large series of specimens of Ciduris verneuiliona from 'lunstall IIill now preservel in the Hancock Museum, Newcastle-on-Tyne, and kindly lent me by the Natural History Society of Northmberland, Durham, and Neweastle-upon-Tyne. Unfortunately the originals of King's figures ( 1550 , pl. vi. ff. $22-24$ ) are not among these specimens, an I Mr. E. Lesmard Gill, the curator of the Hancock Misseum, has not been able to find them. There can, however, be no doubt as to the specific identity of the interambulacrals with those originally described (1515) and subsequently figured by King.

The differences that Desor thoug't couhd be seen in C. verneuiliana were the more granular interradial tract, the more complete scrobicular rings, and the radiating folds around the base of the mamelon. 'These differences are clearly shown in his figures; but in them certain small details of the original figures have been grossly exaggerated. It should be quite clear from the preceding description that the interradial tract is quite as closely crowded with miliaries or with smail tubercles (the granules of Desor), and the serobicular ring is often quite as complete, in Cidaris Leyserlingi as in any specimen of C. verneuitiana. This was admitted by Kolesch, who, however, still maintained that, "die radiären Vertiefungen, welche sich an der Warzenbasis von Eociduris verneuiliana befinden, charakterisieren den letzteren als ):sondere Spezies" (p.661). Now it is a little difficult to understand what Desor and Koleseh meant by these "plis
rayomnants" or "radiüren Vertiefungen." King merely said " Gilenoid circles radiately crenulatel," worls that refur solely to what is here calle d the crembate platiom of the boss, and in this respect there is no difierence bet vecn the German and the: British specimens. If the worls of Kolesch are due to an independent study of interambulacrals from the Magnesian Limestone, he may be referring to the fact that the depressions between the crencllae are occasionally prolonged faintly down the slope of the boss. Such an occurrence, however, is not uncommon in other athicl species, and has been ohserved hy both spandel and myseif in C. keyser'ingi. What differences Lambert thought he could see between these two species, does not appear in his writings: we shall return to Permociduris, which he defines as an Archeocidaril, and it, will then be clear that $C^{\prime}$. esmeniliane can have nothing to do with such a genus.

Miocidaris lieyserlinyi. Two of the most profectly promered fracmenta of interambulacra from the Magnesian Limestone of Tunstall Hill. co. Durham, showing the association and general shape of the plates. In tir. - the scrobiculns are confluent; in fir. 3 they are confluent ab, re, but merely contiguous in the ambital rerion.

The species described by King, though referred by him to Archecocidaris in his text (1850, p. 53 ) and to Palrehinus in the legend to his plate, is in fact a Cidarid. "The subhexagonal form of the plates which. . . principally led" him "to regard it as an Archuceociduris" must be assigned to the imperfection of his specimens. There are before me 11 fairly large fragments of interambulacia, each with two columns, liut none with more. The outer lateral margins of
the individual plates may occasionally be convexly curved, and a slight accentuation of this appearance might give rise to the idea that the plates were subhexagonal or heptagonal. But that these are the adambulacral margins, and that the interambulacrals therefore are pentagonal, is conclusively proved by one portion of an interambulacrum. This consists of two columns, with apparently six plates to each column, and its iname surface is fully exposed (Pl. I. fig. 9). This in all essential details resembles the similar imer view of an interambulacrum of $C$. Kieyserlingi from Pössneck; it has the same denticulate margins and the same thickenings at the peristomial end for the jaw-muscles. It confirms not only the view that the two specimens belong to the same species, but also the reference of that species to Miocideris.

The secondary tuberculation of the interambulacrals from Tunstall Hill displays slight variation. In some the whole extra-scrobicular surface is filled with closely set secondaries of equal size ( Pl . I. fig. 12) ; in others the tubercles of the scrobicular ring are sliglitly, but distinctly, larger than those in the interradial space (Pl. I. fig. 1i) ; in others again the tubercles are less closely set, and bare tracts are seen between them (Pl. I. figs. 10, 13). The development of the secondary tubercles is of course greatest in the ambital region and in individuals of largest size; but apart from this there are individual differences. The relative width of the interradial tract also varies, aud the wider tracts naturally have more tubercles; thus in an interambulacrum 8 mm . wide at the ambitus, the width of the interradial tract, including the serobicular rings, is $2 \cdot 1 \mathrm{~mm}$., and there are 5 or 6 tubercles in that width (Pl. I. fig. 13) ; in another specimen the corresponding measurements are 9.4 mm . and 3.5 mm , and the number of tubercles is 7 or 8 (PI. I. fig. 12).

The secondary tubercles, when well preservod, are seen to have small, apparently imperforate mamelons.

The material from 'Tunstall Hill includes 7 radioles; the one figured by King came from Humbleton ILill and was the property of Mr. Geo. Tate. Of these 7, the longest complete (or almost complete) one is just 8 mm . long, and the greatest diameter of its shaft is 1.1 mm ., this being at about one-third from the distal end. The greatest thickness exhibited by any of these radioles is 1.6 mm ., but this is largely due to the prominence of the thorns. The amulus is prominent, with a diameter nearly equal to that of the shaft-1 mm . in the first-mentioned example; from it a straight slope leads to the crenclate acetabular rim. No definite collerette can be distinguished, but the proximal
region (alout one-thint) of the shaft is smonth, with a fine longitudinal striation. The distal weim is beset with small thorns having a distal rake; in some of the speciment these are not clearly sem, in one they are in distinet longitudinal rows (Pl. I. fig. 15), and in another, where they are particularly foninent, they form curved thanswerse rows (Pl. I. fig. 18). King thought that there were two sorts of radioles: muricate and striate. The specimens are so obscured hy grains of matrix that interpretation is difficult, but I fancy the alove account wresents the facts. 'There was mo doultt a groml deal of variation in the ravien-s of even a single inlivilual, but the genemal charactor of the ratioles agrees with that of thore fomme in the Z-chstwin. There is nothing to warrant the separation of the species.

There is therefore nogront for seporating ! verneniliana and $r$ : Reyserlimen even opecifically. Which trivial name should be adonted is a çuestion mot hitherto diacuseal. K. v. Schaurvth ( $1854,1,152$ ) said "Der King sohe und der Geinitz'she Name sind eleichzoitig ent-tanlen, ein Prioritätert cht besteht alon nicht." This statment is surely mwarrantel. King's 'Cataloge of the Organic Rimams if the Permien [-ic] Rocks of Aorthmierland and Duham' was "pulhishenl by the author" at Newcastle-mpon-T"yne, chume the atternon of saturlay, 19h Augu-t, is is\%. The description of " "iluris Vemeniliame n. su." "s curs on 11]. 6 and 7 of that Cataloulle. Ciluris kyseringi was first described on P' 1f; of II. B. (ieinitz: 'Die Verstemoruncen des deut-chen Zechstinge birges' (heing Heft 1 of (iomitz and (intbier: 'Die Verstcinemu-en des Zech-ainceloirges and Ionthliegenden'). 'The tith page of this 11 it is dated "Dresden und Lei zig, . . . 184s," and a wiew of it appeared in 'Neus Jahrouch tür Mineralogie; Jahre. 1845, 14. 504, 505. These pages are in the fourth of the six parts compesing this Jahirgang, and assuming that the parts were published at regular intervals, this would give August $18 t 8$ fir the date of publication of the review. This part centains letters of which the latest is dated 18 June, 1848 , and it acknowledges the receip,t of publications of which the latest seems to date from April 1848. Most of the works revierred are of 1047 , but a few appeared in the early months of $1840^{\circ}$. One would naturally infer from this that the work of Geinitz was published not later than April or May of $18 \pm 8$. This agrees with a definite statement by R. Howse (Jan. 1857, p. 49) that Geinitz's 'Die Tersteinenungen u.s.w.' was "p,ublished in the carly

[^9]part of April 1815." The trivial name " lieyserlingi" is therefore the one to be adopted.

We have now to enquire in what genus Cindris keyserlingi should be placerl. That it cannot be Ewciduris or Arehrescidaris (=Echinocrinus) has been urged above. Professors Clark and Jackson, as intimated in my opening paragraph;, would refer it to Cidaris, while Mr. Lambert (April 1599, 1. 82) has made it the grenotype of Evtiaris. The former conrse seems to me to ignore improtint structural differences, while the latter course lays unlue stress on a very trifling feature. In the 'Triassic Echinolerms of Bakony'? I have ruferred Cikuris keyserlingi to Doederlem's genus Miociduris. This genus also is regarded by Professor H. L. (llark as indistinguishable from Cidaris, an opinion with which I cannot agree.

## Miocidaris, its Species and Structure.

Since Miocilaris is fully discussed in the 'Triassic Echinoderms of Bakony;' from the nomenclatoral, anatomical, and famistic standjoints, the conclusions there reachet need but a brief summary here. On the other hand it has now become neces-ary to give reason for the distinction of Mi, ciduris from Cidaris.

Winecheris wasestablished by L. Diselerlein in 1587 (p. 40 ), ani from among the species referred to it by him I have solected as genotype Culuris lilipsteini, interpreting that 10
 hame is needed for this species, I propnee IIocidaris cassiani, attaching thereto as lectntyp the interambulacral fragment figured hy Klipstein (le4: ) in phate xviii. fig. 15, and now in the British Museum (regd. 36512).

With Lambert (1goo) I remove (ïnoris sulmolilis to Timalo itlarie, lut include in Miocidurts the species CZ̈laris sulicoronutn, which Duederlein phaced in an unnmed section in.

It is probalite that various species firm the oller Jurassic moks, such as (ivaris amalthei and $\therefore$ arietis included by 1) xacrlein, belong to Iliwcidaris; but I have not personally examined the type-specimens.

Ithe interanthacrals from the Wellen-dolomite of thee Sohwarzwald which Quenstedt (1875, plo Ixvii. fis. 115) referrei to C'iduris grandere are to be placed in MLociduris. Su ahoo is the specimen from Kirchberg on the Jast, which is the holutype of Ciduris coore Quenstelt (1:75, p. 160), pl. Ixvii. tig. 110) ; this is No. 4254 of 'Liubingen Geodogical Ilu-cum, and I owe the opportunity of examining it to the kindness of Professor Koken and Di. F. von Ilume.

Quenstedt himself, as we have already noted, associated Miocidaris coava and M. keyserlingi.

From the Cassian and Raiblian beds of Bakony come five or six representatives of this genus, and for two of them new specific names are proposed in my memoir.

Examination of all this material has led to the following revised and extended Diagnosis of Wiocidaris:-

A Cidarid of moderate size, with the a dradial margin of the interambulacrun sharply bevelled on the inner surface, and usually, if not always, denticulate, thus flexibly imbricating over the ambulacrum. Interambulacral plates relatively few, often wide, with somohicules circular or elliptic, discinct or confluent, with main tubtercles small or of medium size, having cremelate bosses. Podial pores not yoked (?).

The diffornces between this diagnosis and the original one of Doederlein are explained and justified in my memoir. What we have now to consider is the inclusion of Eotiaris. Nefther in 1899 nor in $19(0)$ did Lambert attempt any diagnosis for his new gome, and one must as-ume that he adopter for it Doederle in's diagnosis of Euciduris ( 1587 ), since that was based sulely ou the genotrpe of Eoticris, Li. li-yserlengi. The only difference discoverable between Doederlein's diarnosis of Eocidaris and his diagnosis of Mfocilaris is that the former has "Warzenhöfe ellipti-ch, etwas rertieft, zusummentliessend," while the latier has "Warzenhiofe rumd, schwach vertieft." Klipstein, however, sail of the scrobicule in the holntype of the genotype of Dinciduris (his fig. 15) that it was "seher stark rertieft." Apart from this flat contradiction, the character camot lead to a true generic division, for the species mentionel above present every degree of variation in this respect. The serobicules of lisecidaris keyserlingi are certainly elliptical (m, more correctly, "merilionally compressed "), hut it has heen shown above that they are not always confluent. On the other hand, later species of Niocidaris may have compressed and confluent scrobicules. The change from circular to compressed scrobicules is one that takes place during the growth of an individual, and a similar change may take place in racial history, as does indeed seem to be tho case in Triadociduris. But if so, and in so far as it is of any value, a species with compressed scrobicules cannot be regarded as the ancestor of one with circular scrobicules; therefore if Eotiaris has any validity it camnot be the ancestor of Niociduris, as Lambert maintains. Mir. Lambert may choose wifich horn of the dilemma he prefers; I prefer to drop a genus based on so slight and uncertain a character.

Tre return now to the statements of Professor Lyman Clark (1907, p. 175), who claims Eocidaris Doederlein as a synonym of Cidaris, and says that Miocidaris is " too near Cilaris and Dorocidaris." In two other motes (March and July 1908) I have discussed Professor Clark's application of these generic names, and have accepted Doederlein's relegation of Dorociduris to the synonymy of Cidaris s. str. with genotype C. parillata. Cidaris as restricted by Clark with genotype Cidarites metularia Lam. is the genus or subgenns for which Doederlein (Lov. 1006, p. 100 ) has resuscitated the name Cidarites, but to which he previously (1887, p. 42) aptlied Pomel's preferable name Eucidaris (1883, p. 109). It is, however, unnecessary for our present purpose to consider all the minor details of tuberculation, of radioles, and of pedicellarix, on which the modern genera, subgenera, or sections are largely based. There are far more important differences in the structure of the test. So far as I have been able to ascertain, the sutures between the interambulacral plates in these later genera are plane vertical joints, and do not present the bevele, grooves, and ridges of Miocidaris. At any rate, the sutures between the interambulacia and ambulacra are vertical and notched on the vertical surface for the reception of the ambulacrals; the firmness of this union is intensified by the thickness and solidity of the united phates. In Miocideris, on the other hand, as first pointed out b,y Duederlein, the adradial margin of the interambulacrum is bevelled on its inner surface so as to slide over the ambulacrals, and the grooves, corresponding to the motches in Ciduris, are on the inner face; the ambulacra also thin off to the erges, and are throughout much less solid than in later genera. It is only towards the peristome that the phates thicken, to fom a perignathic girdle, and that the a lradial suture gradually bends to a more vertical position. The perignathic girdle of Diociduris is even then not so stout as that of Cidars and Eucidaris, and the auricular processes with which it is provided are nothing like so large or so well developed as in the later genera. 'laking the broadest construction that anyone nowadays places on Cidaris, it does not seem to me that it can be so extended as to include these Permian and 'Triassic species. And if this be true of c'iduris in a wide sense, it is still more true of it in the restricted senses of Clark, of Doederlein, or of Mortensen.

## Permocidaris.

There is still one genus needing discussion, namely I'ermociluris Lambert (1900, p1, 39, 47), since the genotype
is Cidmis forbesiana Koninck, which Waaren (185.5, p. S19, pl. xcv. figs. (5-16) referred to Eocilaris, and since Lambert also included in his genus two shecies that have heen attributed to Eocidaris, namely Ciluris verneviliana (not C. keyserlingi) and possibly C. coceva Quenst.

Lambert's remarks may be condensed into the following diagnosis:-An Archeocidarid with irreoular, usually suboctagonal interambulacral plates, each with a well-developed tubercle, perforate, crenelate, devoid of lasal terrace, with smooth scrobicule surrounded by a circle of large granules. Radioles fusiform, spinulose.

Since I have bot yet seen the material doweriben hy Thateren, I shall mot waste space on di-cussine his fícuras and descripion. It shonld, however, he pointel ont that 1) Kminek (18f:3, $p$. 4) based the species min rarlioles omly, and that, since these have never heen foum in actual contact with the plates, the ascription of the latter in this species remains an assumption characterized by Whacen as "lighly proballe." It is, of course, on the evilence of the interambulacral plates that the genus is foumterl, and as recrards these I will merely note that in most of Waagen's specimens the complete cutlines were not preserved, so that the shapes aftributed to them are further assumptions. Mreover, it seems impossible to reconstruct an interambulacrum out of plates with the cutlines indicated. 'The arientation of the plates given ly Waagen, when compared with the bevelling of their margins, is fomel to lie quite ont of agreement with the levelling in other genera of the same cenemal character. Wagen's accome of the tuberculation is also perplexing and ineonsistent with his figures.

Consiluring the uncertainty that has on long existed with regurd to the shape of the interamhulacials in C: cornemilanu King, it secms quite possible that 1 . firmaimu is mot really so ancmalous as W'agen's account woull lad whe th =upprec. If the structure of the interambulacra agrees with that of other Archacoilaride (Lepidacilaride mini), then the sole feature in which it can be said with certainty to differ from Eucidaris (s. str.), Archeocidaris ( $=$ Echenocrinus), or Cidurotripus is the crenclation of the parapet. If, on the other land, the interambulacra are of Cidaroid tylue, then reasons for separating the genus from Niocidaris have ret to be supported by adequate evidence.

In the former case it will he olvious to those who have read the preceding remarks on $C$ : vmenilunc King and 1. couca Quenst. that those slecies camot be placed in Leimucidurls. In the latter case C. forlesiana may prore
enngemeric with those two species, and, if so, the mame Permocillaris will be a synonym of Miocidaris.

## Summary and Conclusions.

The genotype of Eucilaris was not fixed by Desor (185j6) when he fommed the geme. Subsequent authors have removed from the genus all species referred to it by Desor except Cideris lucisg inu Sandl). and C. seroliculuta Sandb., which are the only two that arree with Desor's diagnosis. But mo author has yet selected a genotype. Tierefore I select C. Tavispina Sandb, as genotype.

The original specimens of Enciluris lavismina are describe l and figmed, and the origimal of Samtloerger's hl. xxxv. fig. 2 a (18.55) is selected as type (lectn-holotype). The holotype of Cublaris scrobiculate is also redescribed and fisured, and considered congentric with ('. Tavispina. On this evidence Eociduris is provisionally maintained as an independent genus of Archrecidaride ( $=$ Lepidocidaride). No other species are placed in Eocidaris.

C'idur is leysarlingi (icinitz, which has freguently been referred to Eiocideris, is discussed, and fresh details of its structure are given. Numerus topotypes of Ciduris vernemilima King are described and figured, and that species is $f^{n o w e d}$ a synonym of $C$. Reyserlingi. The evidence thas athluced shows that these fossils lelong to Mivcideris Doederlein (1887).

Niocidarts is rediagnosed and M. cassiani nom. nov. ( $=$ Ciduris lilipsteini Desor, non Marcou) taken as genotype. 'The genus is distinguished from the recent Cidaris.

Other species examined and referred to Minciluris are Cidaris sulduronata Minist., C. grancleca Guldt. On the evidence of Quenstedt's specimens (1575), and ('. coccou Quenst. Others are alluded to.

It follows that there is no necessity for Eoticris Lambert, founded to receive Miocidaris keyserlingi.

It also follows that Cidun is cemeuilance King and Co comere Quenst. camot lolong to Permociduris Lambert, a genus that rests on the inadequately described Cielcris jurbesianu De Ron.

## XI.-On the Anatomy and Classification of the Scombroid Fishes. By C. Tate Regan, M.A.

Most schemes of classification of the Teleortenn fishes include a group Scombroidei or Scombriformes, comprising the Scombride and Carangide and a varying number of other families supposed to be related to them. In Boulenger's classification the Scombriformes form a division of the Acanthopterygii, but it is admitted that no good definition
of them can be given, and, as a matter of fare, none of the characters used to separate them from the Perciformes is really distinctive.

The discovery that the Trichiurid senera Lepidopus and Euplenroyrammus do not conform to Boulenger's definition of the Acanthopterygii, as the pelvic bones are remote from the elcithra (clavicles) and only connected to them by a long ligament, has led me to look into the anatomy of the Scombriform fishes.

As a result I find that the Carangidx, Rhachicentridx, Coryphenidse, Bramidæ, and Menidee show no special affinity to the Scombridae and may be placed with the Percoids, but the remainder of Boulenger's scombriformes is a matural group, which still includes so great a diversity of forms as to be with difficulty definable.

It is worth notice that none of the five families mentioned above as rejected from the Scombriformes is known before the Upper Eocene, but that the true Scombroids were abundant in the Lower Eocene (London Clay), from which forms quite as specialized as any living at the present day are known.

This early specialization of the Scombroids makes it necessary to consider whether the indirect attachment of the pelvic bones to the cleithra in the Trichiuride may not be a primitive feature. That this is not the case is shown by the fact that in all the members of the group which have well-developed pelvic fins, the pelvic bones are directly attached to the elcithra-i.e. their anterior extremities are firmly imbedded in the ligament which connects the eleithra above the symphysis*. In Lepidopus and Eupleurogrammus the pelvic fins are reduced to a pair of scales and the pelvis to a small spicular bone, connected by a long ligament with the symphysis ; this condition may be regarded as secondary and due to the degeneration of the fins.

Consequently the Scombroids may be regarded as an early offshoot from the Percoid stem, agreeing with the Perches in most characters, but differing in certain features of specialization.

Before proceeding to the classification of the true

[^10]Scomblorgids some actont of ffer families whirly have hithotw, been placed with them is necessary. These are :-

## 1. Carangida.

The more generalized members of this family fretioler, Noucrufes have the anatomied fharauters of the Serranide, thate beeng motheng in the structure of the cranium, vertelonal columa, or peoteral ards to ditli rentiate them from the latier, whil-t gencra like serombops and Pometomus (Temendron) connect the $\mathbf{t a n}$, familim. In the Carangidae the ramdal pedumele is mom shoder, the camlal flo more widuly fiomed, and the hypual embracei io a preatere extent by the hares of the candal tin-rays than in the sommalie, but the close relationship of the two families is evident.

## 2. Rhachicentridæ.

Rhachicmitm hat a lroad doproond craninm, but the relative pethon of tha bones is is in mormal Pereiformes and is in the Corangilae-i.e., the garimals amb epintic- are
 tals cextend finsmand to the prootice, the pmontis give rise to an ownors rwof for the myolome, athphemmils and a hasi-phomid are prornt, int ino orhitopllemail, the preemasillaries are pmora tile and have a puir of poterior procerses whof slide backwand and formands on each side of a luel on the cthmoid, amb the maxillaios are ospanded distally. Owing to the deprew form of the eranium the basiocipital froms the floor of the formmen maynum, and the exoseipitals are widely separated helow: dhi feature has no importance, as in the Caranside both comditoms (basivecipital entering and excluded irom the foromen magmom) are to be met with.

The pectoral arch is exactly as in generalized Peresids. The rertebral column consists of 25 vertebrae $(11+11)$; there ere 9 pains of rilhs, all but the first of nhich are inserted on short parapophyses: the epipleurals are attached either to the ribs near their pint of insertion or to the rertelma just alove it. The caudal fin is lunate and the rays do not cmbrace the lypural to a greater extent than in Perch. However much the group Poreifomes mat be restricted, I camot sece how this tyle is to be excluded from it.

## 3. Coryphænidæ.

In Ci,rmplam the relative pasition of the cranial bones is as described in Rhuchicentrum.

The skull is chiefly remarkable for the high merlien occipital crest continued forward to above the ethmoid, its anterior portion formed by the fromtals. The ethmoid is hollow d out anterionly for the reception of the rertically placed posterior proerses of the premaxillaries. There are 30 to $3: 3$ vertehre, the precaudals without parapopheses, the ribs and eppleurals inserted together on the centra. 'The structure of the pectoral arch and of the caudal fin is as in the Carangide, to which family the Coryphacnide may be related.

## 4. Bramidæ.

The cranium of Bramu is strikingly similar to that of ('oryphicena. 'The family is distinguished from the preceding by the expanded coracoids and by the stancture of the vertebral column, which comprises 42 to 47 vertebrie and has most of the ribs attached at the extremities of closed hæmal arches.

## 5. Menidæ.

Mene appears to be related to Bromen, which it resembles in the structure of the oceipital crest, but from which it differs in that the eppoties meet behind the supraoceipital. The month is very protractile and the maxillaries are aljnormal, with the inner apophyses much elongated, amol moving in a pair of grooves on the anterior surface of the vomer. This recalls the condition in the Illonirommullii, but differs from it in that the masillarics are non-protractile, each being attached to the well-developed masillar process of the palatine. The rertehre number $2: 3(9+1 i)$ and the anterior ones are much abbreviated; the ribs a.e inserted on transverse processes, except the first pair, which are sessile on the third vertehra, are much entarged, and arm moditiod for articulation with the inner posterior edges of the post-cleithra: the transwerse pro ese of the formh and fifth vertelnae are cularged and support the first pair of ribs from behind.

None of the fire families mentioned above appears to me to be velated to the Scombridee they may all be regardede as more or le-s specialized Per oids. The Caramoda, Coryphandide, and Bramide have a perch-like mon:h arcompanied by a widely forked candal fin, with the hypural bone embraced to a considerable extent by the haines of the candal tin-rays; h, ht that ihis latler featme dors
not really indicate relationship to the Scombride is shown by the fact that Thyrsites has the hypural exposed to the same extent as in most Perches, but is otherwise so similar to Scomber in its anatomy as to leave little doubt that the two genera are closely related.

Recently, in the Introduction to the "Pisces" volume of the 'Biologia C'entrali-Americana,' I instanced three apparently natural groups, each of which included forms with the pelvic bones firmly attached to the cleithra aud others with the pelvic bones remote from them: to these the Scombroids may now be added.

## Order PERCOMORPHI.

## Suborder Scombroideif.

Air-bladder withont upen duct. Maxillaries more or less firmly attached to the mon-protractile pratmaxillaries, which are typically produced and pointed anteriorly *. Cranium with the orbito-rontral portion elongate and the postorthital portion abbervate; parietals selaraterl ly the supraoccipital ; no orbitosphemoill ; hasi-phemoid present ; prooties giving rise to an osscons roof for the myodome. Vertelsal column of solid contra whids are co-os-iticd with the areles. Pectoral arch attachecel to the cranium by a forlied post-temporal : no mesocoracoid; pitery ials more or less regularly hourelass-shapent, 4 in mumber, 3 of them attacherd to the scapula. Pelvic fins of a spine ahd $\bar{j}$ soft rays or variously reduced, thoracic or subthoracie in position, the pelvic bones attached to the clavicles.

## Division I. Trichiuriformes.

Caudal fin-rays not deeply forked at the base, the hypural in great part exposed. Premaxillaries beak-like, free from the nasals; mouth toothed, with lateral cleft; strong anterior canines. Epioties separated by the supraoceipital. Gill-membranes free from the isthmis. Pectoral fins placed low.

## Family 1. Gempylidæ.

Body oblong or elongate, compressed : maxillary exposed: spinous dorsal longer than the soft; anal with 3 simes,

[^11]similar to the soft dorsal ; each pelvic fin of a spine and 5 soft rays or reduced to a spine only ; caudal fin present. Rays of the spinous dorsal equal in numb) $r$ to the vertebre below them, each interneural usually attached to a neural spine; rays of soft dorsal and anal more crowded (except the isolated finlets, when present), about twice as numerous as the corresponding vertebre; pelvic bones separate, anteriorly exteuding forward to the cleithra and firmly imbedded in the ligament between them. Vertebrae $31(15+16)$ * to $53(28+25)$; anterior precaudals without parapophys"s, with sessile ribs; posterior precaudals with ribs attached at the extremities of closed hæmal arches; epipleurals attached to the centra.

Epimnu'a, Ruvettus, Thyrsites, Nealotus, Prometichthys, Gempylus.

The Oligocene Thyrsitocephulus appears to belong to this family.

## Family 2. Trichiuridæ.

Body very elongate, strongly compress ; maxillary sheathed by the preorbital; spinous dorsal, if distinct, not longer than the soft; anal with numerous short spines; pelvic fins reduced to a pair of scale-like appendages, or absent; caudal small or absent. Dorsal and anal rays corresponding to the vertebre, ea hinterneural or interhemal attach d to a neural or hienal spine; pelvie bomes, if present, united to form a slender spicular bone comnected with the cleithra by a long liganent. Vertebre numerous, $100(43+57)$ to $159(39+120)$ or more; ribs feeble, sessile.

Aphanopus, Evoxymepoton, Lepidopus, Benthodesmus, Eupleurogrammus, Trichiurus.

Lepidopus is known from Oligocene deposits.

## Division II. Scombriformes.

Hypural uesrly or quite hidden by the deeply forked bases of the caudal tim-rays. Premaxillaries beak-like, free from the nasals, which are separated by the ethmoid; month toothed, with lateral cloft; no canines. Epiotics separat d by the supraoccipital. Gill-membranes free from the isthmus. Pectoral tins placed high.

[^12]
## Family 1. Scombridæ.

Borly fusiform ; spinous dorsal not lon eer than the soft ; anal with 1 to 3 fectble spines ; losterior rays of solt dorsal and anal forming separate finters; cach pelvie fin of a - pine and $\overline{5}$ branched rays ; pelvic boncos extending forward to the cleithra. Vertebnce 31 to lif: anterion preandak withont parapophyses, with sessile rilis; post rior pracomials with ribs attached at the extremitios of closed haemal arches; epipleurals on the centra.

Scomber, Thummus, Acraulhoryliminn. Giustr chisma, dïי, allied genera commence in the Lower Eocenc.

## Division III. Luyariformes.

IIfpural nearly or quite hieddan by the hase of the caudal fin-rays. Maxillaries broad and thin, attached to the feetble premaxillarics, which are not produced into a beak and hase short ascending processes for attachment to the ecthmod. Month small, anterior: tocth very feblie. Epiotica murd conlarged and mecting behind the -upraocipital, which is rarried forward to atove the ethmond. Gill-membranes hroadly joined to the isthmas. Puctomal fins placed rather low.

## Family 1. Luvaridæ.

23 ventebre; rilos scosile. Post-temporal fuand with the surra-cheitlirum. P'évic bones unitud. Dorsal and anal rays flexible, non-articulated.

Lucorns imperalis, a larere pelagic fi-h re-cmbling a Tumy, is the only known species.

## Division IV. Xiphinformes.

Hypural nearly or quite lidden by the ba-es of the candal fin-rays \% A long pointed rosimm, fomed by the united premaxillaries and by the nasals, the latter mecting in front of the ethmoid and then diverging and tanmine forwarl. Mouth with lateral deft; teeth small or abment. Epiotics separated by the supraoceipital. Gill-memb, anes free from the isthmus. Pectoral fins placed low.

[^13]
## Family 1. Palæorhynchidæ.

Vertebre 50 to 60 in number ; pelvic fins 6 -rayed. Nenual and hemal spines with thin posterior laminar expansions. Scales, if present, thin and cycloid.

Palrorlhynclins aud Hemirhyncheus from Eocene, Oligocene, and Miocene deposits.

 IIistiophorus (b), Xiphius (c), and Xiphiorhynchus ( $l$ ) pmer, premaxillary; mx, maxillary; ne, nasal ; cth, thmoid; fr, fiontal.

## Family 2. Histiophoridæ.

Tertebre 24 or 25 in number; pelvie fins 1 - to 3 -rayed. Neural and hemal spines expanded into strong ove:lapping lamine ; ribss sessile. Scales present. liostrum rounded in transersesection ; teeth present ; a praedcutary bone; navals broadly attached to anterior ederes of fromats; maxillary of nearly equal width throughout its length.

Histiophorus and Tctropturus, perhaps dating back to the Eocene.

## Family 3. Blochiidæ.

24 wert bree. Pelvic fins absent. Nermal and hemal spines not expanded. Ribs apparently atssile. Bonly moved with slightly imbricated, diamome-shaped, homs scouten; two longitudinal senies of enlarged sconte on cath side:

Blochius Iomgirastris, from the Lpper Eoscone of Monte Bolca, attaining a length of one metre.

## Family 4. Xiphiidæ.

26 vertebre. Pelvic fins abocont. Noural and hemal spines not expanded. Ribsinserted on tran-verse proce-ses. Scales absent in the adnlt. Liostmum depresect ; no teeth in the adult ; no predentary bone ; navals extending lack on each side of the ethmoid and just reaching the frontals ; maxillary formed of an expanded anterior and a rod-like posterior portion.

The adult Xiphias g'adius differs considerably from Blochius, but very young specimens clearly show its relationship to the extinct genus. An cxample of nearly 200 mm . in the British II uscum is very similar to Blochins Lungiristris, resembling it in the long slender jaws, the clongate body with the greatest depth just behind the heod, and the continuous dorsal fin. The body is covered with rough, nonimbricated scales, wi:h 4 longitudinal sermes of enlarged scales on each side, 2 corresponding in position to the lateral series in $B$ ochius and the others running at the bave of the dorsal and anal fins.

The Lower Eocene Acestrus mary beloner to the Xiphiidie.

## Family 5. Xiphiorhynchidæ.

Rostrum rounded in transverse section; teeth present; nasals widely separated from the frontals by the broad ethmoid; maxillary formed of an expanded anterior and a rod-like posterior portion.

Xiphiorhynchus of the Lower and Middle Eocene.

> XII.-The Classification of Teleostean Fishes. By C. T'ate Regan, M.A.

Before proceeding to the classification of the Teleostci two questions must be discussed, viz. the rank and the limits of the group.

I have already expressed the opinion that the true Fishes are at least as distinct from the Selachians on the one hand and the Batrachians on the other as any of the vertebrate classes are from each other, and are equally entitled to rank as a class ${ }^{*}$. The class Pisces differs from the Selachii in the presence of two external nasal openings on each side; the reduction of the interbranchial septa; the development of an air-bladder or lung; the beny exoskeleton, typically including paired nasal, frontal and parictal bones, a parasphenoid, an operculum, a series of bones, post-temporal, supra-cleithrum, cleithrum and clavicle, overlying the primary pectoral arch and connecting it with the cranium, scales and articulated fin-rays ; the development of bones in or on the visceral arches, præmaxilla, maxilla, palatine, pterygoids, quadrate, dentary, \&c.; the presence of supra-neural arches (welldeveloped in Chondrostei and Dipneusti, less evident when centra are formed). The Batrachians are separated from the Pisces especially by the presence of true internal nares and of a fenestra ovalis, the modification of the paired fins into pentadactyle limbs and of the hyomandibular into the stapes, and the absence of endoskeletal supports and dermal rays from the median fins.

Whilst recognizing the importance of the characters which distinguish the Pisces from the Selachii, I have hitherto been so conservative as to regard these groups as sub-classes only, using the name 'Teleostomi for the former. The groups which I formerly recognized as orders of the sub-class

* Regan, Proc. Zool. soc. 1906, p. 7el, and Biol. Centr.--Im.. Pisces, p. viii (1908).

Telenstnmi, viz. Clinndrostei, Telenstei, Crossopterygii, aud Dipneusti, I now regard as sulb-classes of the clasis l'iscus. 'Ihese four sub-classes may lee arranged in two series: in the Actinopterygian series (Chomlrostei and Teleostei) the dact of the air-bladder opens dorsally or derso-laterally into the alimentary canal, the branchinstegals retain their primitive serial arrangement, and the supports of the paired fins are either in the form of a series of paralles pherysiophores eath of which is segmented into a basal and a ratial portion or are modified from this plan by a simple process of concentration and reduction; in the Crossoterygian series ( Crossup) terygii and Dipmeusti) the opening of the phemmatic duct is Ventral, the branchiostegals are replaced by a pair of gular plates, and the paired fins are more or less lobate, with their supports tending to the biserial arrangement with asial basalia.

The Teleostei are well maked off from the Chondrostei by the absence of elavicles ane of pelvicualials, the reduction in number of the dorsal amd anal fin-rays, si) that cach has its own pterygiophore and the shontoning of the uptumed axis of the candal fin, which is homseercal or abloreviate heterocercal. 'Thus definil they include the Ilolostei, a group which cannot, in my opinion, be maintained.

The ordinal names are not oomed on any delinite plan, but usually have some reference to the peculiaritics of the group; it seems to me useful ahways t., form subontinal names with the termination -uidei, and when tamilios are arrange! in divisims or superfamilies th give these groups names ending in -formes.

> Synopsis of the Orders and Sub-orders of the Sub-class Teleostei.
I. Spleuial well developed.
A. Vertebral centra incomplete, or with alternating pleuro- and hypo-centra in the caudal region .. 1. Protospondyli.
 by little expanded hemal spines.
No endochondral supraoccipital; parietals united by suture; opercular bones complete

1 a. Amioidei.
An endochondral supraoceipital; parietals united by suture ; opercular bones complete

1b. Dapediodei.
No endochondral supraoccipital ; parietals separated by a median dermal bone; suband inter-operculum absent

## 1 c. Pscnodontoidei.

2. Premaxillaries separated by an ethuo-romerine rostrum; lower lobe of caudal fin supported by a singlo mutch explanded hemal spine. . . . . . . . . . . . . . . . 1d. I'achye ormoidui
B. Vertehral centra complete, amular or biconeare; no separate pleuro-centra and hypo-centra .... 2. Aspidorhynchii.
C. Vertebral centra complete, opisthocoelous; no separate pleurocentra and hypo-centra
3. Ginglymodi.
II. No splenial; an enduchondral supaoccipital ; vertebral centra complete.
A. A mesocoracoid $\dagger$.
4. No Weberian ossicles; maxillary entering the gape to a greater or less extent and not acting as a lever for the protraction of the præmaxillaries; mesethmoid unpaired.
5. Isospondyli.
a. Frontals united by suture.
a. Mouth not protractile.

* Parapophyses autogenous or parietals separated by supraoccipital.
Parietals present
4 a. Clupeoidei.
P'arietals absent
$4 b$. Stomiatoidei.
** Parapophysesco-ossified with centra ; parietals meeting, separating frontals from supraoccipital.
Entopterygoid articulating with a lateral peg of the parasphenoid

4 c. Osteoglossoidei.
On each side of the skull a lateral foramen or
cartilaginous area superiorly and a resi-
cular diverticulum of the air-bladder
inferiorly
4 d. Notopteroidei.
On each side of the skull superiorly a lateral
foramen lodging a resicle which has lost
its commection with the air-bladder
4 c. Mormyroidei.
ß. Mouth protractile; maxillaries not articulated to the craninu ................. $\pm f$. 1'hract.lemoid.i.
b. Frontals united to form a single bone; gill-membranes joined to the isthmus........ $4 \%$ Gonorhynchoidei.
c. Fromala completely erparateil; gill-membames joined th the isthmus ................. 4 h . Cromerioidei.
2. Weberian ossicles present. . . . .... 5. Ostariophysi.

Parietals distinct; pterygoids, symplectic and opercular bones all present; anterior vertebre more or less distinct

5 a. Cyprinoidei.
Parietals united with supraoccipital; no metapterygoid, symplectic, or suboperculum ; anterior vertebræ co-ossified .. 5b. Siluroidei.
B. No mesocoracoid.

1. Parapophyses autogenous.
a. Parietals united by suture; mesthmoid umpaired; phyanclistic ...................... . 6. Ifcteromi.
b. I'aictals separated by the supravecipital; pairal dermal ethmoids; physostomous .... 7. Haplomi.
Pectoral pterygials normal. . . . . . . . . . . . . . 7 a. Esocoidei.
Pectoral pterygials represented by a cartilagimous phate

7\%. Hallinide.
$\dagger$ Ahsent in mom Arentinitat and silurila and in the lialaxiada and Ilaplochitonida.
2. Parapophyses co-ossified with centra.
a. Physostomous $\ddagger$; pelvic fins, if present, abdominal.
a. Promaxillaries nearly excluding the maxillaries from the oral border; body eel-shaped; no paired fins; vertical fins confluent
8. S'ymbranchii.

Pectoral arch attached to the skull by a forked post-temporal

8 a. Symbranchoidei.
Pectoral arch free from the skull ; no posttemporal

8 b. Amphipnoidei.
$\beta$. Premaxillaries absent; maxillaries articulated with the fixed ethmo-vomer; quadrate fixed; pectoral arch freo from the skull ; body eel-shaped.
9. Apodes.

Large interbranchial slits; tongue present;
opercular bones well developed......... 9 a. Anguilloidei.
Small interbranchial slits; no tongue ; opercular bones reduced

9 b. Murmoidei.
$\gamma$. Iremaxillaries absent ; maxillaries meeting anteriorly and suspended by the integument from a movable ethmoidal rostrum ; quadrate movably articilated with the hyomandibular ; pectoral arch far hehind the skull; body cel-shaped. . . . . . . . . . . . . . . 10. Lyomeri.
i. Premaxillaries excluding maxillaries from oral border; parapophyses short or absent; epineurals present ; orbitosphenoid present and parietals united by suture or posttemporals nearly meeting above supraoccipital; an adipose fin
11. Iniomi.
c. Premaxillaries excluding maxillaries from oral border; all precaudal vertebræ with strong transverse processes; no epincurals; no orbitosphenoid; parietals separated by supraoccipital; post-temporals lateral; nu adipose fin . .............. 12. Microcyprini.
b. Physoclistic; pelvic bones not directly attached to the cleithra §; orbito-sphenoid absent or vestigial; maxillary not protractile.
a. Lower pharyngeals completely united; fins without spines . . . . . . . . . . . ..... . 13. Synentoynathi.
$\beta$. Lower pharsngeals separate.

* On each side a dermal plate (ectocoracoid) which in the adult is united by suture to the cleithrum and coassified with the coracoid. 14. Thoracostei.
** No ectocoracoids.
$\dagger$ Snout tubiform; parietals absent; pterotic extending downwards to basioccipital.

15. Solenichthyes.

Mouth toothed; gills pectinate; anterior vertebræ elongate, with transverse processes on each side united to form a shelf :
lower 3 pectoral pterygials enlarged .. 15 a. Aulostomoidei.
$\ddagger$ Some Cyprinodontidie have recently been shown to be phrsuclistic.
§ Except in the Luciocephalida and some Anabantidat, which serm clearly related to forms with ablominal pelvic fins.

$\dagger \dagger$ Snout not tubiform; parietals present; pterotic not reaching basioccipital.
§ Body enclosed in bony rings ; mouth inferior.
16. Hypostomides.
§§ Body naked or scaly; skeleton well ossified; ahomocercal caudal fin.
$\phi$ No suprabranchial organ ; anterior rays of dorsal and anal spinous; pelvic lins abdominal, with- out spines, each of 7 to 9 rays.
17. Salmopercce.
$\phi \phi$ No suprabranchial organ; a spinous dorsal; pelvic fins abdominal, each of a spine and 5 branched rays .... 18. Percesoces.
Pectoral fin and pterygials normal ..... 18 a. Mugiloidei.
Pectoral fin with a lower detached portionformed of free filaments; pterygialsrepresented by a plate attached to theedge of scapula and coracoid18b. Polynemoidei.
$\phi \phi \phi$ A suprabranchial organ.
19. Labyrinthici.Fins without spines, the pelvics 6-rayed;suprabranchial organ not labyrinthic;air-bladder simpleFins usually with spines, each pelvic of aspine and 5 soft rays or further reduced ;suprabranchial organ labyrinthic; air-bladder bifureated posteriorly19 b. Anabantoidei.
§§§ Body naked or scaly; skeleton in great part cartilaginous; a homocercal caudal fin; no finspines.
Pelvis represented by two separate cartilages far behind the cleithra; pectoral pterygials normal. . . . . . . . . . . . . . . . . . .
Pelvis unpaired, cartilaginous, articulating above with a cartilage embraced by the cleithra; pectoral pterygials represented by a cartilaginous plate
21. Chondrobrachiz.
§§§§ Body naked or sealy; skeleton well ossified: no homocercal caudal tin; opisthotic extending downwards to the basioccipital.
22. Anacanthini.
 coracoids ; pelvic fins without spines, often with numerous rays; maxillary free, protractile. 23. Allotrioynathi.
a. Budy deep; skeletnn well ossified; an occipital crest; lower pharyugeals toothed; post-temporal forked; an orbitosphenoid.
Frontals nomal, in conitact below with the
mesethmoid and orbitosphenoid; ribs sessile ; pelvic bones articulated to the greatly expanded coracoids; tach pelvic fin of 15 to 17 ravs

23 a. Lamproidei.

Frontals forming thie lateral walls of a chamber, the floor of which is formed by cartilage containing the mesethmoid and orbitosphenoid ossifications; ribs on parapophyses ; pelvic bones not articulated to the coracoids; eacis pelvic fin of 8 or 9 rays

23 b. Veliferoidei.
及. Bodr elongate; skeleton feebly ossified; no occipital crest; lower pharyngenls toothless; post-temporal simple.
An orbitosphenoid; epioties meetiug behind the supranccipital ; palatine and pterygoids present ; neural and hremal spines present; body ribbon-shaped

23 c. Trachypteroidei.

d. Physoclistic; cranium symmetrical; an orbitosphenoid or pelric bones directly attached to the cleithra; pelvic fins usually with more than 6 rays, the first of which may be spinous; maxillary attached proximally to a process of the palatine
24. Berycomorphi.

An orbitosphenoid
24 a. Berrcoidej.
No orbito ephenoid
24b. Zeoidei.
e. Physoclistic ; cranium asymmetrical ; pelric bones directly attached to the cleithra; fins without spines.

## 25. Heterosomata.

f. Phrsoclistic; cranium srmmetrical; pelric bones directly attached to the cleithra $\dagger$; each pelvic fin of a spine and i) soft rays or still further reduced; no orbitosphenoid.
u. Post-temporal more or less distinctly forked, attached to the epiotic abore and to the opisthotic or exuccipital below.

* Spiuous dorsal not forming an adhesire disc.

> 26. Percomorphi.
 attachment is assumed to be due to degeneration.

## $\dagger$ No bony stay for the præoperculum.

Pelvic fins subthoracic, thoracic or jugular, each of 5 or 6 rays, the first of which is spinous; ribs, if present, normal; premaxillaries more or less protractile; opisthotic not enlarged

26a. Percoidei.
Pelvic fins subthoracic or thoracic; ribs normal ; præmaxillaries not protractile, typically produced and pointed; opisthotic not enlarged

26 b. Scombroidei.
Pelvic fins thoracic; ribs expanded, forming a series of juxtaposed rings enclosing the air-bladder

26 c. Kurtoidei.
Pelvic fins thoracic ; opisthotic enlarged, extending downwards to the basioccipital. 26 d . Gobioidei.
Pelvic fins jugular or mental, each of 1 to 4 rays, the first of which may be spinous; parasphenoid sending up a wing on each side which is joined by suture to the frontals.
$\dagger \dagger$ Third suborbital produced to or towards the prooperculum § ........... $26 f$. Scorpænoidei.
** Spinous dorsal modified into an adhesive disc placed on the head . . . . . . . . . . 27. Discocephali.
$\beta$. Post-temporal simple, rod-like, directed outwards, at right angles to the horizontal, backwardly directed supra-cleithrum ; cranium depressed ; pterygoids reduced to a single small element united to the quadrate; ribs attached at the extremicies of sessile epipleurals; an adhesive ventral disc bounded posteriorly by the postcleithra, which meet in the middle line and are attached to the pelvi-
28. Tenopteri.
$\gamma$ Post-temporal, if present as a distinct element, small, simple, suturally united with the cranium; ribs absent ; gill-openings reduced.

* Pelvic fins, if present, subthoracic or thoracic; parietals
absent .............. 29. Plectognathi.

Post-temporal distinct, suturally united with the pterotic ; supra-cleithrum vertical ; pectoral pterygials not enlarged 29 a. Balistoidei.
Post-temporal co-ossified with the pterotic ; supra-cleithrum oblique or horizontal; lower three pectoral pterygials enlarged

29 b. Tetrodontoidei.
** Pelvic fins, if present, jugular; parietals present; pectoral pterygials elongate.
30. Perliculati.

Spinous dorsal normal; epiotics separated by the supraoccipital ; epipleurals present; 4 or 5 pectoral pterygials
$30 a$. Batrachoidei.
Spinous dorsal, if present, modified in structure and position, the anterior rays on
§ Except in the Comephoridx, which have the skeleton feebly oesitiod, Ann. \& Mag. N. Hist. Ser. 8. Vol.iii.
the head; epiotics meeting behind the
supraoccipital; no epipleurals ; 2 or 3
pectoral pterycials
30 b. Lophioidei.
§ No pont-temproal : pretwal arch attoched to the vertebral column
31. Opisthomi.

The synopsis wiven above is a mollifieation and amplification of one which formed part of a paper on teleostean chas-ification read to the section of systematic Zoolose of the Internatimal Zonlogical Congress at Boston in 1907, and which will no donht he publistimat at some future date.

Later on I hope to give mone detailed accounts of the anatomy ant clar-ifination of smme of the less known group: but within thie limit of the pacsent paper ouly a few brief nots sh atme point ; which ne 1 clucidution are possible.

## Isospondili.

In some extemal characters Retropinna is intermediate between (ismerus and I'optroctes. lí tropinna, Sulincx, and Alierostoma are Argentinide which have no mesocoracoid. The Aventimia, Hapholitmilx, and Galaxidax are extrems ly smilar in ortenlogy, dentition, and in the absence of oviducte, and are undoubtedly closely related.

It is pussibfe to unamtain the order Isaspondyli, with the addition of the Haplochiomilre and Galaxidae, by taking into consideration the momb-structure, the maxillary chterimg the eap to a Geater of less rat nt (almost excluled in Haplocatonition), and the unpuiren ethmeil. As thas

The cetace ni = Entombution fall into the divi-ion stomiatoidi ; they a_ren with the Somiatilie in the structure of the skull and of the mouth.

The Ksmida. knos of to me from extomal characters only. show conitemble remblance to the: Gourhyuchibe, and may pertain to this order.

## Heteromi.

Boulenger has painted out that the Lipog nike are intermeliate in fin-struture between the Mal saurilie and Notacanthilæ. These three families constitute the order Heteromi, from which I wouk exclude the Dereetilee, in my opinion probably belonging to the Iniomi, and the Fierasferidx, which are withut question specialized Brotulide.

In skeletal characters Ilelusurus and Netucanthus agree in that the ortito-rostral part of the cranium is elongate, the parietals meet, opisthotics, basisphenoid, ali-phenoids, and
orbitosphenoid are absent, the parasphenoid unites with the spenotic (post-frontal) in front of the prootic, the post-temporal is simple or ligamentous, the scapula is lamellar and imperforate, the præcaudal vertebre have autogenous parapophyses, epineurals are present, \&c.

## Haplomit.

The Haplomi as now restricted comprise only the Umbridr, Esoci lx, and Dalliidr, a very primitive group agreeing with the Isospondyli in mouth-structure, but unique in the character of the paired ethmoids.

## Apodes.

I have define? the Apo.les as lacking premaxillarie:, and I am very sceptical as to their presence in Derichulhs. It we neglect this character, Derichthys is very similar to tho Anguillidae, in many of which (e. s. Congrr) there is what may be a premaxillary dentition distinct from that of the vomer, although there is no separate premaxillary bome. Dr. Gill does not tell us that he dissected hispucimen of Derichthys serpertimus in order to ascertain the limits of thes premaxilaries, and it seems not improbable that he may have iniferred the gresence of these bones as separate elements from the presence of a well-defined premaxillary dentition.

The Cretaceous Anguillavidæ and Urenchelidæ have a distinct caudal fin, and small abdominal pelvic fins are present in the former.

## Lyomeri.

The presence of parietals, the transverse processes ankylosed with the centra, the restricted gill-openings, \&c. indicate the derivation of the Lyomeri from the Apoles and not from the Stomiatoids. The Synaphobranchidæ approach them in their rather broad skull, long slender maxillaries, backwarlly directed suspensorium, absence of pterygo-palatine arcade, \&c.

## Iniomi.

The order Iniomi includes the Aulopidæ, Synodontidæ, Odontostomidæ. Paralepidæ, Alepidosauridæ, and Myctophidæ; probably also the Rondeletiidæ and the extinct Chirothricidæ and Dercetidæ. The name Iniomi may be retained for this group, although in Aulopus the forked posttemporal is firmly attached to the epiotic above and the opisthotic below; this generalized type has two supramaxillaries and shows considerable resemblance in cranial
structure to the Elopidx; the orthosphenoid, however, is rather anomalous; it is placed far forward and forms an interorbital septum extending from the parasphenoid to the frontals, whilst posteriorly paired inferior ridges of the frontals separate it from the alisphenoils. The protractile premaxillaries exclude the maxillaries from the oral border, and this feature distinguishes Aulopus from all Isospondyli. In Iniomi other than the Aulopida the post-temporals nearly meet in the middle line above the supranccipital, but are attacher by ligament to the epioties, the maxillaries may become reducel and closely attached to the premaxillaries, the orbitnsphemod tends to disappear, and the parietals may beome separated by the supraccipital (Myctophidx).

## Microcyprine.

The order Mierocyprini inclules the Cypmomontide and Amblyonside, usually considered to be allied to the Eisocidee, which they resemble in fin-structure.

## Thoracostei.

The order Thoracostei compnises the Gastrosteidze and Aulorhynchidæ. Swimerton * has shown that the dermal plate which appears as part of the coracond is in reality a distinct element. I camot accept Jungersom's view that these fishes belong to the Scorponvilei, although I readily admit that the Aulostomoids are more distinct from the Thoracostei than I recently considered them to Lo:

## Solenichtifyes.

In a valuable memoir Jungersen $\dagger$ has pointed out the features which show that the Anlostomode, Comtriscoide, and Lophobranchii form a natural group, to which the ordinal name Solenichtiyes, recently proposed ly me for the Centriscoids only, may be applied.

## Hypostomides.

The Pegasidee show certain resemblances to the Scorpenoid Agonidre and Dactylopteride, but they also exhibit some important differences from them, especially in the truly abduminal pelvic fins.

## Salmoperce.

I am unable to find a pneumatic duct in the Percopsidæ, Which have hitherto been said to he physostomous. The

- Quart. Journ. Micr. Sci. xlix. 1905, p. 363.
$\dagger$ Vidensk. Selsk. Skr. (i) ri. 190 s, p. 41.

Aphredo leridæ are precisely similar to them in their anatomy, and these two closely related families constitute the order Salmopercæ.

## Labyrinthici.

The suborder Anabantoidei comprises the Luciocephalide and Anabantidæ, the latter including the O-phromeni la, which I am unable to recognize even as a distinct family, although Boulenger has widely separated them from the Anabantoids.

## Malacichthyes.

The order Malacichthyes is equal to the family Icosteide, i. e. Icosteus and Acrotus ${ }^{*}$, of very uncertain relationships.

## Chondrobrachit.

This order comprises the Ateleopidar, a very remarkable and isolated group of fishes.

## Percomorphi.

In some members of this order the lower fork of the posttemporal is very short (e. !/. Acanthurita), in others the upper limb may be expanded and suturally united to the skull (Agonide, Trigidie) ; further, the interspaces between it and the lower limb may be filled in by osseous laninæ, so that the post-temporal may form an integral part of the skull (e. g. Callionymus).

Of the suborders of the Percomorphi the Percoidei is by far the largest, and its classification is a matter of some difficulty. It is equivalent to Boulenger's Perciformes, after the exelusion of the Berycoids and Osphromenida, with the addition of the Stromateidæ, Tetragonuridæ, Carangidie, Rhachicentride, Coryphænidæ, Bramilæ, Menidx, Percophiidæ, Ammodytidx, 'I'rachinidx, Champsoduntidre, Leptoscopide, Uranoscopidæ, Parapercidæ, 'Trichonotilse, Nototheniide, Callionymidæ, and Agriopidæ.

Hitherto the indirect attachment of the pelvic bones to the cleithra has usually been regarded as a primitive feature, but it is difficult to see why this should alway's be so. It is scarcely open to question that the ligamentous comexion between the post-temporal and the epiotic in Synoclus is derived from a direct attachment, as secn in Aulopus. It the pelvic fins can migrate backwards from a thoracic $t$ 's a su!)abdominal position by elongation of the pelvic lones, which

[^14]seems to have happened in the Cirrhitiformes, why should they not do so by elongation of the ligament which bimets the pelvic bones to the cleithra? In the cases of the Stromateidx and Tetragonurde and of the Cempylide and Trichiuride it is in the more specialized and degenerate forms that the pelvic bones are attached to the eleithra by a rather loner ligament. In the Labyrinthici and Berycomorphi it is quite different; in each of these the forms with the pelvic bones remote from the cleithra (Ophiocppholus, Polymicia) are the more generalized, differing from the rest in that the pulvic fins are composed of articulated rays only.

The suborder Scombroidei inchles the divisions Trichiur:formes, seombrilomes, Lavarionmes, and Xiphiifurmes; a more detailed account of this group is given in a separate paper.

## Xenopteri.

I ams quite in agreement with Or. (fill as to the omlinal distinctness of th: G bifencilae, and I am unable to apmeciate their supmseal clase mationship to the Callionymita; the latter are not very different from the Parapere lee an I Nototheniidx.

## Plectognathi.

The bones namel parietals in my memoir on this grou: may inclute those elements, but should preferabiy be termed epiotics.

## Bibliography.

The following deal with the classification of Teleostean Fishes in general; the numerous memoirs dealing with the anatomy and classification of particular groups are not included :-

## PROCEEDINGS OF LEARNED SOCIETIES.

## GEOLOGICAL SOCIETY.

November 4th. 190s.—Prof. W. J. Sollas, LL.D., Sc.D., F.R.S., President, in the Chair.

The following communication was read:-
'On the Fossil Plants of the Waldershare and Fredrille Series of the Kent C'oaltield.' By E. A. Nerrell Arber, M.A., F.L.s., F.G.s.

At the boring at Shakespeare Cliff, Dorer, Coal-Measures were reached in 1590 at a depth of 1100 feet, and subsequently penctrated to a depth of about 2.25 feet. Thirteen seams of coal, varying in thickness from 1 to 4 feet, were pierced. Coal-Measures wore struck at 1304 feet at the boring in Waldershare Park, and pierced for 1260 feet more. Fire seams of coal, rarying from 1 foot 4 inches to 5 feet 2 inches in thickness, were struck. The boring near Fredville Park reached Coal-Measures at $131 ; 3$ feet, pierced three seams of coal, and was continued to a depth of 1513 feet. The specimens of plants collected from the Waldershare and Fredrille borings are dealt with in detail, and compared with plants found at Dover and in other localities in Britain and abroad. The more abundant and characteristic species are common to Waidershare and Fredville, and lead to the conclusion that the heds belong to the same horizon. The majority of species tabulated are either contined to the Cpper Coal-Measures and the Transition Series helow, or are Middle and Lomer Conal-Measure furms which are known to occur in the Transition Series. Indeed, all but two plants have been recorded from the last horizon. Thus the beds are the homotaxial equivalents of the Newcastle, Etruria, and Black-Ban! hurizens of Nurth Statfordhire, the Hamstead Beds below les:3) fe-t in suth staffordshire the Coed-rr-allt lieds and Rua:on Marlo of Denlighshire the Ardwiek Series and Berls abow the limannad Four-Fuot Coal in South Lancashire, the Lower Pemant (irit of Sull W:ales, and the New Rock and Yolster Series of Somerset. The data with regard to Dover are too scanty for certainty. but they seem tuindicate approximately the same horizon as the two nther Kentish lovalities. The manority of species are also common to the highest zone, or the 'Charbons Gras,' in the J'as de (alais. The flora of these rocks, and of those on the same tectonic line. helongs to the lomer of the tro great Continestal zones of the Tpper Carboniferous-the Westphalian: and the higher zone, the Stephauian, is unrepresented in the Mendip-Artois series of basins. But, as this axis is followed from east to mest, it appears that continuously higher horizons are met with.

## MISCELLANEOUS.

## The Type of Cidaris.

## To the Elitors of the 'Anmals and Mayazine of Matural IFistory.'

Gextlearex,-In my reply (in the June number of the 'Annals') to Dr. Bather's (in the March 'Anmals') discussion of the type of Cillaris I completely overlooked the really conclusive argument on the sulject, to which he refers in one paragraph but faiis to emphasize. Dr. Mortensen, of Copenhagen, has now called my attention to it hy letter, and I bey you will allow me the space to acknowledge my surrender.

While it is true that lichions cinturs, Le, of 1754, is probalily Pholltacanthus bucontasa hut is not centainly identifiable, there is n ) escape from the fact that Bechimes cellutis, L., of 1761 ('Fauna Suecica $)$, is the species now universally known as Domoridur prepillatn. Lime's referencetn (ianlthieris figures 1 ) and E, plate 1 ins, and omission of all other references. taken in comexion with the statement that the species necurs in Aortregian seas, leaves no romm for doult on the point. Such being the case, Io oroctiluris pmpilluta should hereatter be known as Cidaris cilarios (L.), as sagerested by Bather, while alyyssicalu and the other species of lomorichuris become Cillaris alyssicola, de. The senus now called Ciduris becomes Eucidaris, Pomel, 1-5.3, who, however, Ac-ignated no type. Di. terlein in 1est uses Encielaris in Pomel's sense, and as he mentions onetulatia first, we may rery conreniently consider that species the genotrpe. I regret that by orerlooking the 'Fauna Suecica' I have needlessly prolonged an untortunate controversy.

Hebert Lyman Clark.
Museum of Comparative Zoology, Cambridge, Mass.,
Nov. 30, 1908.
N゙ore.-Since Professor Lyman Clark has most courtenusly transmitted this letter through me. mar I express my satisfaction that at any rate four of us have come to an agrement abont Cidnris s. str.? Further, I see no objection to the adoption of Euciluris, Pomel, with genotype E. metuluriu. We may well suppose that the "trois especes rivantes " of Pomel's list were Cidaris metularia, C. tributoides, and C', thmearsi. Let us hope that Professor Düderlein will give up Cidurites, and return to his earlier choiceEucidaris.
F. A. Bather.

Brit. Mus. (Nat. Hist.), 10th Dec., 1908.

EOCIDARIS AND MiOCIDARIS

## THE ANNALS

AND

## MagAZINE 0F NATURAL IIISTORY. <br> [EIGHTH SERIES.]

No. 14. FEBRUARY 1909.
XIII.-New Species of Indo-Malayan and African

## Family Hesperidæ.

## Celanorhinus zea, nov.

q. Uniform dark olive-brown above; palpi below, pectus, legs beneath, and segmental bands on the underside of the abdomen greyish ochreous: fore wings with a broad discal band much as in C. Ahencta, Moore, but cut short and square on vein 2, with a small spot attached on the middle which runs below the vein, the band, which does not quite touch the costal line, white, tinged with ochreous and semilhyaline; three subapical whitish dots, the middle dot inwards and attached to the upper dot, which is minute: hind wings without markings. On the underside of the fore wings the discal band is produced to the hinder angle (which it does not quite touch), the extension being caused by an adjoining large spot of the same colour as the rest of the band: hind wings without markings: antennæ broken.

Expanse of wings $1 \frac{6}{10}$ inch.
Khasia Hills; one example.
Apparently a perfectly distinct form ; the band on the underside of the fore wings is very similar to the band on the underside of the fore wings of C. affinis, Elwes, which 1 al:so

Ann. \& Mag. N. Hist. Ser. S. Vol. iii.
have from the same locality, but the uppersile is quite different, and the sulpapical ifots of that species are almost linear and joined together.

## Parnara enteblea, nov.

$\mathrm{o}^{7} \mathrm{f}$. Of a uniform very dark hankikh-brown colnur, very nearly fure hlack; fore anl midhle lage and hind tarai orance-cherems heiceath: fore wimger above with two diecal lyadine spots, the lawer the larers, slighly prolnend ontwards at it = lomer (mil) throw -mall subpical lyadiae sposs, the midde spent inwands; in the Cemal. there is an in lisimet discal lower minute spot. On the underside, which is as hack tas the ughervite, ile inuer margimal space of the fore wings is broadly pale, the spots are as above; no other markings above or below.

Expanse of wings $1 \frac{1}{2}$ inch.
Entebbe, Uganda ; 7 o, 1 ㅇ.
There is a mate from Uranda umamed in the B. M. ; in one example the middle subapical spot is absent.

## IIasora almea, nov.

ot. Of a miform dark dive-hown colour above ; palpi on the mulesside with white and hrown hairs, the collar helow almost pare white; baly and legs bown : alolomen with thin whitish segmuntal lambls heath: fore whes alove with a rather promment, ormilyadine, white, central liscal spot in the interpace beis on bins :" aml 4 ; 1 n oner markings ahove; the fore wiura lahw with a hrad metallic bluegreen costal hand from the hase to one-lifind form the apex, the interime of the wing filled nh with an acntely cut triangular dark bown slace, without any pale line limitug its outer sile, the di-cal spot smaller than it is above, and amother and still shatler white s?ot how it and on the immer side of it : hind winus with a vely thin and straight discal white line, not touching the costa and slightly thickened before the anal snyte, where it is hroken by the upper portion of the large hack patch; a thin white anteciliar short streak rumning from the hack patch; all the wing from the band to the base thick with metallic blue-green scales.

Expanse of wings $1_{10}^{?}$ inch.
Brunnei, N. Borneo; one example.
The hind wing on the undersite is marked very similarly to II. meala, Swinhoe, but that form has no anal black patch and is of a different shape ; clluet has the shape of chromes.

## Hasora amboinensis, nov.

d $f$. Both sexes of a uniform dark olive-brown coleur above, without any markings ; palpi below and pectus greyish white, thorax and abdomen below with greyish-white hairs: fore wings below with a metallic blue-green broad costal land from the base to one-third from thie apex ; the imer space of the wing dark brown, limited by a transverse pale shade from the costa to the middle: lind wings with a broad, white, neanly straieght discal band, from the costa near the apes to the anal angle above the large black anal pateli; it is nearly even for twoothieds, then narrows, and slightly enlarges again above the pateh, is then broken, and has a white spot on the abdominal margin adjoining the black patch, and a short thin anteciliar white streak; the whole of the portion of the wing on the inner side of the band is metallic blue-green, and there are a few hlue-green scales outside the band.

Expanse of wings $1, \frac{9}{10}$ inch.
Amboina; one pair.
A female is in the B. MI. mixed up with II. alexis, Fallr., but its shape is quite different from that of alexis. Wattson very properly separates alexis from chromus, Cram., and it is difficult to understand why they are mixed up, together in tlee 13. M. collection over the name alowis with other forms into what might be called a real " job lot," merely on account of their superficial resemblance to one another.

## Family Plutodidæ.

## Synegia secunda, nov.

$\delta^{7}$. Pale yellow; palpi orange above, an orange spot on the frons: fore wings with an olive-brown stripe along the costal margin, a black dot at the end of the cells of both wings; fore wings with antemedial and postmedial transverse thin bands, continued across the lind wings as subbasal and medial bands; a sulmarginal line, continued across the upper dise of the lind wings, where it runs into a thick nearly straight band which crosses the dise of the wing from alove the anal angle to the outer margin below the apex ; all the bands olive-brown, and the spaces between the bands on hoth wings sparsely irrorated with olive-brown atoms; black marginal dots on both wings. Underside much paler, no irrorations, but the hands more or less faintly indicated.

Expanse of wings $1 \frac{1}{10}$ inch.
Padang, Sumatra ; one example.

## Family Ennomidæ.

## Hypochrosis mimaria, nov.

d. Shafts of the antermer whitish, plumes black: wings ahove and thorax dark olive-green grey, costa of himl wings hroadiy pale pink: fore wings with a broat transverse greenish-llack hand edered with whitish, extendisg upwards from the hinder mare in a little before the midnle, expanding ahove its midule, with a pale excaratiom on its "plow enter below the costa, which it does not reach; its inner clge is slightly corved inwards above its centre and the ruter elge is decply shous: : on the himl wing there is a very large oval-shaper gremish-black patch, edcen with whitish near the alntrminal margin, atenting from lows the millile is the hase, which it dus not reach; both winge are inomated with dank greenish atoms and the cilia are pinkish grey. On the mulersile the buty, luss, and wings aro lorigit ereyinh pink; the tore wings lraally pale on the himber matgin, amt there are indications of a broad lmownish band from the midille near the hinder margin, gradually narrowing upwards to the apex of the wing.

Expanse of wings $1 \frac{6}{10}$ inch.
Padang, Sumatra; one example.
Belongs to the festivaria group.

## Hypochrosis lubricata.

Omiza lubricata, Warren, Nov, Zool. ri. p. 65 (1899).
 (1901).

Flores.
I overlooked Warren's description when describing this Geometer.

## Family Macariidæ.

## Calletora distorta, nov.

§. Ochreous grey, uniform in coloration above ; markings above much as in the common Indian Luxiaria olliquata, Moore; the shape of the hind wing, however, instead of being rounded, is convex below the middle, making the anal angle somewhat produced. (On the underside the bands are somewhat similar, but the discal band of the hind wings is distorted, conresponding to the shape of the outer margin; the fore wings are uniformly greyish brown, with a large pale, nearly white, apical patch; the hind winge are pale grevish
ochreons, making the bauds very prominent; marginal line on both wings below dark brown, with slight outer projections at the vein-ends; cilia nearly white; the second free vein of the hind wings bends downwards at its middle and terminates at the same point as vein 1 near the anal angle.

Expanse of wings $1 \frac{1}{2}$ inch.
Entebbe, Uganda ; one example.

## Genus Loxotephria.

Loxotephria, Warren, Nov. Zool. xii. p. 13 (1905).

## Loxotephria padanga, nov.

ठ . Dark pinkish grey, the fore wings darker than the hind wings and of a red tint; both wings irrorated with white, the closeness of the irrorations making the costal and outer portions more or less smeared with white: fore wings with an indistinct, antemedial, straight, transverse line ; b.th wings with postmedial and submarginal straight lines, the former commencing from the ablominal margin a little beyond the middle and the latter from near the anal angle, both extended to the apex of the fore wings, all the lines dark dull red and the cilia of the same colour. The underside is much paler and has a strong ochreous tinge, and is irrorated with pink, and both wings are crossed by parallel red straight lines, medial and discal, and there is some dark suffinsion towards the outer margin of the fore wings and a large suffused red subapical spot.

Expanse of wings $1_{1} \frac{1}{0}$ inch.
Padang, Sumatra; one example.

## Family Boarmiidæ.

## Ectropis discolor, nov.

ő. Dull pale ochreous; palpi brown above ; some brown dots on the upperside of the shafts of the antenne; abdumen with a black tuft of rather long hairs bencath, near the base : wings rather thickly irrorated and smeared in parts with olive-brown, leaving a somewhat indistinct paler central band; four transverse olive-brown lines across both winges at equal distances apart, all simous and mostly outwardly dentated ; a more indistinct submarginal line and b,tack marginal spots. Underside pale, nearly whitish; costar of fore wings with blackish spots; a very broal, transverse, pale blackish-brown discal land, slightly narrowing (小wnwards, with indications of its continnation acruss the himd
wings; a brown lunule at the end of each cell and black marginal spots.

Expanse of wings $1 \frac{1}{2}$ inch.
Padang, Sumatra; one example.

## Family Geometridæ.

## Lophochlora annuligera, nov.

d. Anteme ant froms orangs ; heal, themax, ant wingo above and below pale geen; abiomen, thorax bolow, and legs ochreous white: wings thinly clathed ; costal line of fore wings orange ; a rumul white spot, each embainimg a black lunule, at the end of tise coll of cach wise: a large white spot in the dise alove the milhle; varmus other smaller white spons here and there on the outer podion of the fore wings, two on the hinder margin and one at the apes of the hind wings; cilia of both wings white, spottal with orange.

Expanse of wings $1 \frac{2}{10}$ inch.
Entebbe, Uganda ; one example.

## Family Sterrhidæ.

## Synelis acutangulata, nov.

d. White, custal line of tore wings ochreous brown; a hack dot at the end of the cell of the hind wings ; two ochreous-grey lines acruss boh winge, the first medial, sinmous, and indistinct, the other acutely anculated: himd

- wings with a similar submarginal line; buth wings with black marginal duts in the inter-paces. Underside pure white, without markings.

Expanse of wings $1 \frac{1}{10}$ inch.
Entelbe, Uganda; three examples.

## Induna pura, nov.

8. Upperside of the shafts of the antenne white, lower side and pectinations ochemus grey; tarsi ochreous grey; otherwise this insect is pro white above and below, without any markingz.

Expanse of wings 1 inch.
Entebbe, Uganda; three examples.
Family Callidulidæ.
Callidula nemoga, nov.
ヶ. UE a uniform dals ochrous-brown colyar; palpi
leneath, pectus, less, and abilomen bencath orange: fore wings with a broal discal orange band from the mindlo of consta to the himalur angle, storiping short of both; on the underside this band reaches the costa and runs narrowly along it to the hase ; a small sulfusel ochreons mark at the anal angle of the hind wings.
Expanse of wings $1 \frac{4}{10}$ inclo.
New Giunea, Mlilne Bay (type in B. M.), and one fomale from the same locality in my collection.

## Cleis atata, nov.

of f. Upperside : body and wings dark blackish brown: fore wings, with a large orange-ocheons pateh on the outer margin above the hinder angle, with its imer side rom led: hind wings with a broad orange-uchreons marginal band, Which covers half the wings; cilia of lonth wings black. Uuderside : winus black; an ochreuns struak on the ensta of fore wings at the base, which runs into an ochreous sul)costal spot in the middle; a large ochreons patch on the onter margin alove the hinder angle, with its immer elge produced into an acute ande ; an ocheons spent in the male near the point of the angle, which is absent in the femate, but there are two or three small orhreons mark; below the sulcustal spot ; antennat ivelow marked with ochreous; palpi, body below, and legs ochreons, the lergs with black stripes.

Expanse of wings, of $1_{10}^{50}$, ㅇ $1_{10}^{6}$ inch.
Ké Island ; one pair.
Somewhat like Cocureolu, Swinke, from Cbi, and Co. posthcalis, Guerin, from Port l'raslin, inat the fermer hats an ochreous discal band on tho fore wines, belovz and the latter has the ochreons on the fore wings below in the dise away from the outer margin.

## Family Limacodidæ.

## Scopelodes anthela, nov.

8. Antema, palpi, thoras, and fore wiugs glowsy greyish brown ; palpi. with the brush whitish, some black hairs at the tips; abdominal half of hind wings orange-ochreons, the outer half greyish brown, paler than the fore wings ; cilia of both wings whitish, no makkings: abdomen orange-vechresus, with dorsal black bands on the last five segments; anal tult black: wings below much paler than they are above, and all the veins whitish: body orange-ochreons; ablomen with a diuplicate row of black spots, the space between whitish; leys greyish brown, with white laurs, the tarsi with thenk tip:s.
f. Much paler; in some examples the fore wings are almost ochreous; in all the examples the hind wings are entirely more or less ochrerns; the spots on the abolonen below are similar, but above they are more or less obsolescent.

Expanse of wings, o 2, of $3 \frac{2}{10}$ inches.
Singapore; $100^{\sigma}, 3$ of in the B. M. and in my muscum (types in B. M.).

Sandakan, 1 o in B. M.
Java; 1 of in my coll.

## Family Sarrothripidæ.

## Hyblaca asava, nov.

ठ. Upperside: body and wings dark olive-brown ; aibiomen with indistinct whitish segmental bands: fure wing with a blackish medial thin band, straight from hinder margin to end of cell, where it is acutely angled to centre of costa, with black markingz, and there are also some black marking: near the apex of the wing: hind wing with three very large, almost square, anange-schreous spots, one below the middle of the costa, anether below it and a little outside of it in the dise, and the thind tuwands the anal angle ; there are also some pale ochrous haiss on the ablominal area of the wing and an ochreous mark at the base. On the underside the wings are maked in a very cunous manner; the fure wing has two short yelluwish-white streaks at the base, two thick ones from the costa fone entral and the other cutes) ruming halfag down the wink; the limker marein is hradly whitish: the hime wing is all white, timgel in parts with gelluw, with a blakkish marginal bonder with brown dots above its inner side; a black sireak upwants and downwards flom the hase; a large black ringlet from the mildle of the cozta, with a very small ringlet an a curled mark at its lower end: body yellow; legs yellow streaked with black.

Expanse of wings $1 \frac{1}{2}$ inch.
Mindoro, Philippines (type in B. M.).

## Family Quadrifidæ.

Genus Leistera, nov.
Antemx smooth, as long as two-thirds of the costa; palpi smonth, reaching vertex of head; thorax somewhat hairy: fore wing with long floceulent hairs from melian vein below, filling , up the entire cell ; venation of both wings as in Cuthlide: fore legs with thich rather long hairs; mid and Lnimilege with fans of long hairs on femora and tibia, the
former with one pair of terminal spurs, the latter with two, the outer twice as long as the inner.
'I'ype L. (Catephia) mulchristrigata, Bethune-Baker, from New Guinea (Nov. Zool. xiii. p. 253, 1906).

## Ophiusa roulera, nov.

o. Antennæ black ; palpi, frons, head, and thorax above and below bright ochreous; abdomen and wings purplish black; fore wings with an erect white medial band, with a round small outward projection above the middle, and inwards in the middle, the lower half of the band broader than the upper; the band is not so broad as in O. schraderi, Felder, from Australia, and is without the two black spots that are so conspicuous in that species; a white mark on the costa outside the band and some white flecks on various parts of the wing: hind wings without markings ; cilia of both wings pure white. On the underside the wings are uniformly black, cilia as above; legs ochreous; tarsi brown, with whitish rings.

Expanse of wings $1 \frac{7}{10}$ inch.
Ké Island ; one example.
Can be easily distinguished from O. schraderi, Felder, or (). lutizona, Butler, by its unmarked pure white cilia; in both those species the cilia are variegated with large uniform black patches.

## Genus Ugana, nov.

3. Palpi upturned, long, second and third joints of similar lengths, first about haif as long as the others, all of about the same thickness, covered with short bristles, the end of third joint blunt ; antennæ two-thirds the length of the costa, with short bristly bipectinations of even length almost close up to the tips, where they shorten suddenly; mid tarsi with one pair of spurs (a very long and a very short one), hind tarsi with two pairs; body slender ; abdomen extending beyond the hind wings and curving upwards: fore wings with costa a little bent towards the apex, hinder margin nearly as long, slightly concave in the middle, outer margin somewhat rounded: liind wings with the outer abdominal margins rounded; veins 3 and 4 , and 5, 6 , and 7 from the lower and upper angles of the cell; hind wings with vein 2 from one-thind before end of cell, 3,4 , and 5 from lower end, 6 and 7 from upper end.

## Uyana piana, nov.

ठ. Uniform olive-lirown, paler and shadd with ochrecns beneath; reniforms small and pale, orficular formel lyy two curved lines, which in some examples are joined at both ents ; a straight black line from the ablominal margin onethird from base to ore-bliod from apose of fure winge, whore it is shaplly angled inwands on to the costa, and a waved and somewhat outwandly dentated black line juat outside the straight line; a blachish suffued amb indi-tinct discal hanel somewhat close to the margin, which contains a row of whitish dots on the reins; the dits run accoss bohe wingte, but the blackish shade is confinal to the fore wings ; some very minute whitish dots clow to ils margin; mercimal line black; cilia black, with a whitisli hasal line. Undervide with two outwardly curved lonwn melial lines across buth wings and a pale thick discal line.

Expanse of wings 2 inches.
Entebbe, Uganda ; five examples.
There are two examples in the I). Mr. numamel from Uganda and Sieraa Leone, (Luadrifid Drawer 42.
XIV.-The Cullections of Willium Julen Purellell, J). C.L., in the Hope Dedertment, Osivic? Uriversity Museum.

Westwood's list (N. 51) gives an individual captured a. 24.8.27, which is probably a copyist's mistake for tho date of 1095 . He also mentions " one without a number."

## Phyciodes teletusa, Godt.

904. I. 25. 10. 25. $q=$ 1096. Minas Gerä̈s. " $P$ [quilio]. At Discoberto, near João Pedro's house.
This specimen bears Westrood's number N. 87.
28.10. 25. $\quad q=1097$. Minas Geraës. (As 635.)
905. 11. $25 . \quad$ ㅇ $=1098$. Minas Geraës. (As 559.)
1. 3. 26. $\delta=1099$. Rio de Janeiro. This specimen bears Westwood's number "Nym. 89," and is the only one under this number.
Westwood's list (N. 87 and N. 89) agrees.

## Phyciodes sejona, Schaus.

6. 8. 27. $=1100$. "Campinas." Between Mogy Mirim and S. Paulo.
This specimen bears Westwool's number "Erye, ${ }^{\text {2a }} 70$, "
and is given in his list of Erycinilx. Unfortunately it is in a very bad state of preservation, so that its determination camot be quite certain. However, there are traces of certain markings on the undersite which have led to its inclusion in this series.
1. 10. $27.2=1101,1102$. S. Joaquim to Sapezál.
30.10.27. $3=1103,1104,1105$. Sapezál to Conceição.

13z. 30. 10.27. = 1106. Sapezál to Conceição.
25. S. 2S. $=1107$. Retiro to Goyavétra. "On the road." This specimen bears Westwoul's number "Nym. 91"; his list agrees.
Professor E. B. Poulton, F.R.S., and Mr. R. Trimen, F.T.S., have very kindly examined these specimens, and they agree that they conform to Schaus's description of $I$. sejona. Unfortunately the type is in America, so that comparison has been impussibie. The species is remarkahly near $l$ '. tcletusa, and, in fact, may turn out eventually to be only a more northern form of it. 'llre whole genus is composed of such variable species that it is most desirable that brecding shouk be undertaken on a large scale to cistablish each species on a satisfactory basis.

Phyciodes burchelli, sp. n.
B~. 24. 10. 27. = 1108. Meiaponte to S. Joaquím (Juari. Alves). The type of the species.
2S. 10. 27. = 1109. S. Joaquím to Sapezál.
?().10.27. = 1110. Sapezál to Coneciçĩo. This specimen bears Westwood's number N. 90.
25. S. 25. $3=1111,1112,1113$. Retiro to Goyavéira. "Un the road."
Westrood's list (N. 90) agrees.
This species is umamed in the British Museum, where it is placed next to $P$. teletusa; the Godman-Salvin Collection contains a long series also tmamed from Chapada and south Brazil, and a few specimens cxist in the collection of Mr. H. Grosc-Smith.
(1108.) Uprerside. Gromud-colour dark fusenus-brown ; a wide orange-tawny land from imer margin of hind wing to near costa of fore wing, broken at apex. Fore winn: from imner margin an oran ge-tawny band, the breadth of which is a little less than half the length of the inner margin, to a little above the third median nervule, leaving externally a narrow lind-marginal burder of ground-culsur, in middle of which are three orange-tawny lumular markings situated respectively
betreen the submedian nervure and the first merlian nervule, between the first and second median nervules, and just above the third median nervule. The orange-tawny band is broken off about the third median nervule by a narrow streak of ground-colour ruming obliquely fiom costa to centre of hind margin and widest at costal end, leaving an apical marking of orange-tawny which runs from the subcostal nervure to the second melian nervule; it is widest in centre and is ronghly triangular in shape. A faint orange spot at exterior end of cell. Cilia of the ground-colour. Hind wing: orange-tawn band of fore wing continued across hind wins, superiorly slightly broader and occupying a good half of the himd wing, and extending to inner margin, leaving a little wider lind-marginal border of gromed-colour than in the fore wing. Exterior edge of orange band is markel by a row of faint ground-colour lunular markings which merge into the hind-marginal border at second subcostal nervule; hind-marginal border itself traversed by a series of linear orange-tawny lunules, one in each internervular space, the largest being albove the first subcostal nervule. Cilia as in fore wing. Hind margin crenelated.

Underside. Light taway ground-colone very much paler in hind wing, with brown subapical and hind-marginal markings. Fore wing: tawny ground-colour slightly darker towards middle and end of cell, a little beyond which is a dark brown oblique bar from end of first subcostal nervule to hind margin at end of second median nervule; outer edge of bar straight, inner edge concave, the hind-marginal end broadening out over anal angle. External to this bar a light fulvous one, almost broken in middle, the outer edge of which is irregrlarly defined, and wider towards hind margin. This is succeeded by a lilac-brown apical patch, with a short oblique narrow whitish mark on the costa. A narrow lunulated brown-fulvous edging to hind margin. Central portion dull orange-fulvous, corresponding to orange-tawny band of upperside. The apical markings are variable. Hind wing: basal part appears slightly darker through presence of very delicate and irregular light brown transverse lines. A hindmarginal land of lilac-brown, growing lighter towards each extremity about first subcostal nervule and about first discoidal nervule. In this band a comected series of whitish lunules from costa to anal angle ; on inner edge of hand five small dark brown inwardly pale-margined spots, of which the two middle (between the radial and second median nervule) are largest.

Exp. al. 31-36 mm. (type 33 mm .).
'Jype, specimen 1103 in Hope Department, University Muscum, Oxford.

Jistribution (based on six specimens taken by Burchell and on a scrics in (G) lman-Salvin (Collection). Rio Tusutins, province of Goyaz; Chapala and South Brazil. In the Briti-h Muscum thore are fire specimens ( 1 子 from Nauta, Upper Amazons, Pern, :3 1 of fom Eenador) which are very near it, if not actually the same species.

Compared with $I$. cluvia, G. \& S. (Biol. Centr.-Amer., dihopal. pl. xxi. fig. 21, 22), on the uppersile limiohelli buats a close res mblatere th it, but the tasny limmlar line in the hime mangin of the himd wing in hincheri is wanting in c'mein, and the himl-marzimal band of fosous heown in cincine cions not reach the ansl angle as in lusi helli. The un lemel les
 hrown hime wing, and the fore wing is of the same chlome except for two orange-tawny patches.
$l^{\prime}$. Kletuse, on the other hand, is nearly related to burchelli on the underside as well as the upper.

## Phyciodes claudina, Esch.

10. 11. 26. = 1114. Rio de Janeiro. (As 670.)

Bz. 12. 3. 26. = 1133. Pio de Janciro. "Aqueltret." $28.11 .27 .3=1134,1135,1136$. S. Joarquin to S'apezál. 30. 10. 27. $4=1137-1140$. Sap zail to Cunceiçã.
$B z+30,10,27 .=1141$.
a. 21. S. 2¢. = 1142. Hiceir". "A!l at the" rivulet near the house at Retiro." (As 844.)
Thiis specimen beas TVestwem's number " Nym. s6."
Eza.+ 2k, 5. 29. = 1143. "Silva," Between Italóoa and Baião ; north of the F'alls of Guaríba.
p. 31. 5. 29. $=1144$. Baião.
p. 31. 5. 39. = 1145. "Dylva." This date must be a slip for 31. 5. 2!. Baĩ̃o.
It is, perinap, worthy of rote that " 39 " for " 29 " is the only mistake of the kind so far detected among some 1200 specimens labelled by Burchell. A second will be found on 1221.
20. 9. 29. $2=1146,1147$. Parí. S.E. of S. Jozé.

Westwood's list (N. 8ŏ and N. 86) agrees.

## Phyciodes fragilis, Bates.

a. 24. S. 28. = 1148. At Retiro. "Ali at the rivulet near the house at Retiro." (A.s 844.)
W'estwood's list (N. S:5) agrees, though he placed it in his list of the preceding species.

Phyciodes pedrona, sp. n.
220. I. 25.5 10. $25 .=1149$. Minas, Gerac̈s," "P[qpilio]. At Discoberto, near João Pedro's house."
The type of the species.
The specimen bears Westwood's number (N. 95) ; his list agrees.

A single specimen exists, umamed and without any data, in the B. M. collection.
(1149.) Tepersite. Dark fuscons-brown ground-colour relieved with tamy-yeilow spots, an imegular line of which crosses the hind wing from costa to imuer margin. Fore wing: from costa to inner margin a broken line of six tawny-yellow spots; the first is situated on the costa about the end of the second subcostal nervule, the next two between
upper radial and third median nervule ; the remaining three continue the line 1 millimetre nearer the base, one spot below each median nervule, the midlle one being slightly the largest: this line is succemde externally by a similarly irregular line of five smaller spots ; the first is very faint amd is phaced letween the fir-t and second ralial norvules. Close to himd margin batwen third amd seconl melian nervals a tawny yellow sumt. Basal portion relievel homaller watgetawny spots. Cilia of estomel-mbur. Hind winy: from centre of costa to a puint two-thinds the lagith of imacr maryin a concave lime of soyn internembler tawny-sellow spots. Indfwas between this anl himl margin a -milat row of sis small datk lemwn inwar Ily tawny-anar, ined apurs-n spont on costa in this suries. Nit far from hime margin a row of seven almust limear tawny yellow lonules. A tuw small orance-tawny spots in hasal iegion. Vilia as in fore wises.

Undersile. Iright tawny-yellow eromul-colour, markel by dark brown patch between median nervules in fore wing. Fore wing: from a point on costa between first and swoml subcostal nervulos to thicd median nervule a namow pale ochreons macular stripe, contimmal to inner margin 1 millimetre nearer to hase, hrodening at innor margin towarls anal angle. This stripe is succeelell by a large apical prateh of slightly richer tawny yellow. Below this and between median hervules a dark fuscous-hrown path prolonemd upwards by two similarly colourel spets heowen radial nervules, and ifwnwarks by a small spit lechow first melian nervule. A line of thee pale ochmoms sp ts parallel to hime marein from helow second radial nervale to Lelow secoml median nervule; the mi Whe one occuries centre of fa-conthrown pateh. Extemal to pateh and homering on hind margin between third and second median nervules a large pale ochreous spot. A faint hind-marginal border of dark tawny lunules. Hind wing: basal region pale ochrous, with irregular broken sub-basal and median indistinct yellow macular streaks. Exterior region tawny yellow, relieved by a line of small dark fulvons inwardly yellow-margined internervular spots from apex to anal angle. Hind marginal row of fulvous inwardly yellow-margined lunules. Cilia of slightly lighter ground-colour than on upperside.

Exp. al. 25 mm .
T'ype, specimen 1149 in Hope Department, University Museum, Osford.

Distrilution (based on this single specimen). The southern part of Minas Geraës, near Rio.

The upper surface of $P$. jedionu is near to that of $P$. thetros,

Drury. Compared with a single specimen in the Hope Collection from Mexico, tharos is 5 mm . larger in expanse of wings ; the spots of the hind wing are larger, and two large spots appear in the basal region which are unrepresented in pedrona. The fore wing of tharos differs considerably iu having a wellmarked and regularsubmarginal row of six spots, while pedrona has a faint and irregular series of five; tharos, again, has a pale oblique streak beyond cell and another broken pale oblique streak from cell to inner margin, both of which are absent in pedrona. There are also more fulvous markings at base in tharos. On the underside of fore wing three fuscous-brown markings appear in tharos, one along the outer edge of cell, another just above anal angle, and a third in centre of imer margin, in contrast to the single submedian fuscous-brown marking in pedrona. The two species are, on the whole, very markedly different.

In the British Museum a single specimen of pedrona is placed next to P.simois, Hew. (Permambuco and "Brazil"). In simois a larger black marking is apparent behind the lower part of the hind margin; but rows of white spots take the place of the pale yellow spots in pedrona, and in the fore wing. of simois there are white and rufous spots at the apex and onter margin which are absent in pedrona.

Ertsia eunice, Hew.
16. 6. 29. $=1150$. Pará.
29. 7. 29. = 1151. Pará.

Specimen 1151 bears Westrood's number A. 5 and "Eresia Esora"; his dates agree, but he gives this species the name of Eresia esorca and places it among his list of Acræinæ.

## Eresia langsdorfii, Godt.

28. 10. 25. = 1152. Minas Geraës. (As 635.)
'This specimen bears Westwood's number A. 6, and "Eresia Langsdorfii."
1. 10. $\because 5 .=1153$. Minas Geraës. "In the forest on the S.E. side of S. João de Nĕpomucéna."
1. 11. 25. = 1154. Minas Geraëz. (As 559.)
'I'his specimen bears Westwood's number A. 6.

27.3.29. = $1199 . \quad$,

Westwood's list (A. 20) onl"y gives six specimens in the whole of the above series. He placed it among the Acrevir $x$ and named it "V'unillce." Probably a supplementary list exists on a small slip of paper, as in the case of Ayraulis juno, but this has yet to be found.

## Agraulis (Dione) juno, Cram.

$B=$.5.5. V. [19. 10.25.] 4=1200-1203. Minas Gelaëт. "Papilionida." At Discoberto, Oct. 15 and 21.
Westwood's list, in his own handwriting, gives five, indicating that one specimen has disappeared or has lost its label. $B z .+$ '19. I. 23. 10. 2.) $=1204$. Ninas Geraüs. "I'apilio." At Discoberto, Oct. 22 and 24.
This specimen bears Westwond's number A. 22.
Bzz. + 901. 11. 25. 10. 25. $2=1205,1206$. Minas Geraës. "P[apilio]. At Discuberto, near Juão Pedro's house."
30. 10. 25. $=1207$. Minas Geraës. "(In the forest). On the N.E. side of the arraial of sin João de Nëpomncéna."
4. 11. 2J. $2=1208,1209$. Minas (ierä̈. (1:559.)

The list in W'estwood's handwritine, which is probably perfect, gives three specimens of this date.
$B z+$ 7.11. 25. $=1210$. Minas Geraës. 16. 2. 26. $2=1211,1212$. Oryan Mountains. 29.1.27. $=1213$. Vicinity of S. Paulo. 24. 10. 27. $=$ 1214. Mitiaponte to S. Joaquím (Joaq. Alves). $b_{z}+$ 28.7.29. = 1215. Pará. "28.7.27" in Westwood's list.
The data of this species not only appear, as A. 22, in Westwood's Acrainæ, but also separately on a small slip of paper. In the first of these lists, which is very incommlete and in a clerk's handwiting, he describes the species as " like Taniller, but darker," while the second list, which is altogether in Westwool's writing, and prohably perfect, bears the heading "Dark under winged Fritillary."

## Colcenis julia, F.

Bz. 144. II. [16. 8. 25.] $2=1216,1217$. Rin de Janeiro. "I'ap [iluo]. Above the ''eresa Convent ; and on the woody hilly [hills] along the Aqueduct."
Bz. 33\%. I. [15. 10. 25.] = 1218. Ninas Cieraë.. "Pqpilio. At the Discoberto do Antonio Velho... (14夕)"
This number (144) refers to specimens 1216, 1217, which Burchell thus recognized as the same species. This is given in Westwood's list.
Bz. 554. III. [19. 10. 25.], $3=1219,1220,1220 \mathrm{~A}$. Ninas Geraës. "Pap [ilio]." (As 1200.)
$B z+994$. VIII. 27. 10. 25. $7=1221-122 \%$. Ninas Geraës. "Papilio. At San Juão de Neponucena and on the road from Discoberto."
Opposite number 0 ?'f Burchell gives eight specimens date ?
27. 10. 25 , making no mention of specimen 1221, labelled in England 26.10. 25, and also bearing the Brazilian number 994. The latter date is evidently a clerical error, and is interpreted above as 27.10 .25 . Compare 1145.
4. 11. $25.2=1228,1229$. Minas Geraë3. (As 559.)
29. 12. 25. = 1230. Rio de Janeiro. Catombí-Bárra Vermélha-and Rio (Jomprido.
a. 25. 2. 26. $=1231$. "Frexal." Organ Mountainc. Burchell sometimes wrote "Frexal" for "Frechál."
7. 3. 26. $5=1232-1236$. Rio de Janeiro. "At Catombi." This date is given in Westwood's list, but only for two specimens.
No. 1234 bears Westwood's number A. 16.
$B z .+$ 7. 3. 26. $=1237$. Rio de Janeiro. "At Catombí." 10. 3. 26. $=1238$.

Bz. 10. 3. 26. $=1239$.
Bz. 12. 3. 26. = 1240 . " "Aqueduct."
Mentioned in Westwood's list.
12. 3. 26. $2=1241,1242$. Rio de Janeirn. "Aqueduct." 13. 3. 26. $3=1243,1244,1245$. Rio de Janeiro. One specimen mentioned in Westwood's list.
16. 3. 26. $=1246$. Rio de Janeiro. (As 647.)
20.3. 26. $6=1247$-1252. Rio de Janeiro. "Along the Carioca Aqueduct."
$B z .+25.8 .27 .=1253$. Ollaría to Rio Pardo.
25. 8. 27. = 1254.
3. 3. 28. $=1255$. Goyaz. "Caught in the town by the rio Vermelho by C[ongo]."
28.4.28. $=1256$. Goyaz. (As 748.) Mentioned in Westwood's list.
$B z .+14.4 .29 .=1257$. Porto Reál [Naçionale]. $B z .+15.4$. 29. $=1258$. Porto Reál. " 12. 8. 29. $=1259$. Pará.

Westwood's list (A. 16) only gives six specimens of this species in his list of Acræinæ. His description of it is thas :"Cethosia? orange red with oblique brown bar in f. w." We may surmise the existence of a second list, now missing, giving the remainder of the dates, as in the case of the previous species.

Colonis pherrusa, Linn.
Bz. 14.4.27. = 1260. In the Campo beyond Bóa Mórte. Near S. Paulo.
'Ihis specimen bears Westwood's number A. 15, and his list adds another example, captured 13. 5. 29 at C'arolina,
an R. Tocantins, between Porto Real and Pará. Westwoud deseribed this as a "Cethusia (Caralina?) red buff with brown bars and white spots on margin of h. w." He placed it, as A. 15 , among the Acrainæ.

## Metamorpha dido, Linn.

12. 3. 26. $=$ 1261. Rio de Janciro. "Aquestuct."
1. 3. 26. $=1262$. lion de Janciro. Along the Canioca Aqueducl. (See 917.) "P'apilio: The green species frequents the tops of trees are [and] flies genemally ligh alove reach." [This cvidently reters to this species, though the specimen bearing the date 17. 3. 26 does not bear the no. 1057. The latter, however, is borne ly a specimen of luphlion atucus, Diury.] Westwond's list gives one specimen bearing 10.57 and two with 17.3.26. The former and one of the latter are now missing.
$B z=20.3$ 3. 26. $=$ 1263. Rio de Janeiro. "Along the Carioca Aqueduct."
1. 4. 26 . $=1264$. Rio de Janeiro. "In the valley of Catumbi."
This specimen bears Westwood's number A. 19.
$B=+1316.17 .2 .29=1265$. Ponto Rival. "Feering on the flowers of the Wultheria bushes (r. II. 56.32x)." (See 663.)
1. 17. 2. 29. $=1266$. As above.

Westwod made two lists of this species, in one of which he memions only one specimen on this date, white four are recorded on the other.
2. 3. 29. $=1267$. Porto Reál.
7.3.29. $=1268$. Porto Ruál. "The green papilio loses much of the beauty of its, greecis culor within a day or two after being caught." It is certain that the "green papilio" is Metemorp hea dieto, Limn, as Burchell gives the above note on a specimen dated 6. 3. 29. The specimen is now lost, but is mentimed by Westwood in his list of this species. See also 1262, where this Papilio is described as "the green species." The green pigment is not contained in scales, but exists between the two membranes of the wing, being almost certainly the blood or hæmolymph in a solid state, and the colour due to metachlorophyil or some other modified plant-pigment. Green markings caused in this manner are also found in Victorina stelenes and several true Papilioninæ of the sarpedon group, also in the Pierine
genus Nepheronia, although in this case the green colour is concealed by the opaque superficial scales. The rapild change of tint noted by Butchell is clearly associated with this unusual development of pigment between the wing-membranes, and it is probably caused by desiccation.
Bz. 9. 3. 29. = 1269. Porto Reál.
10. 3. 29. $=12$ \% . Porto Reál. "Lepidoptera began to apear more numerous in the end of Feby, and since the beginning of this month they appear abundant."
Westwood's list mentions another specimen captured un this date.

| $B z .+13.3 .29 .=1271$. | Porto Reál. |
| :--- | :---: |
| $18.3 .29 .=1272$. | $"$ |
| $B z .+21.3 .29 .=1273$. | $"$ |
| $23.3 .29 .2=1274,1275$. | $"$ |
| $B z .+23.3 .29 .=1276$. | $"$ |
| $B z .+25.3 .29 .=1277$. | $"$ |

Westrood's list does not mention any individual caught on this date, hut one taken 22.3.29, -probably an erroncons rendering of 1277 .
28. 3. 29. $=12^{178}$. Porto Reál.

Bz. + 28.3.29. = 1279. Porto Reál. 22.4 . 29. $2=1280,1281$.
$B z .+22.4$. 29. $=1282$.
7. 8. 29. $=1283$. Pará.

Westwood's list adds two more individuals captured at Porto Reál 26. 2. 29 and 6.3. 2\%. Siee note on 1288.

The data of this species appear, as A. 19, in Westwod's list of Acræinæ. Opposite the very imperfect records Westwood had written "Ceth. Dido." Another list, on a small slip of paper, is in Westwood's handwriting, and this contains all the data here recorded except those of 1261 . This separate list is headed "Dido."
[To be continued.]

> XV.-The Char (Salvelinus) of Great Britain. By C. 'I'ate Regan, M.A.

Four speries of Char have hitherto been described fiom the lakes of (ireat Britain : viz. Salvelimus killinensis, the Haldy of Loch Killin in Inverness-shire; S. strunnensis; the Struan
of Loch Pannoch in Perthshire; S. willuahthii, the TVindermere Char ; and S. perisii, the Torgoch of the mountain-lakes of Camarvonshire. In spite of much that has been written to the contrary, these four species are quite distinct, as will be seen from a comparison of the descriptions given below and from the diagnostic characters shown in the following synopsis :-
I. Snout obtuse; luwer jawr rounded ant-riorls, shorter than the upper. Interorbital width 3 to $3 \frac{1}{3}$ in the length of head, considerably more than the diameter of eye; least depth of caudal peduncle $\frac{2}{3}$ to $\frac{1}{2}$ the length of head; 182 to 215 scales in a longitudinal series

1. killinensis.

Interorbital width $3 \frac{2}{3}$ to 4 in the length of head, scarcely more than the diameter of eye; least depth of caudal peduncle $\frac{1}{3}$ to $\frac{2}{5}$ the length of head; 158 to 180 scales in a longitudinal series
2. struanensis.

## II. Snout conical or subconical in the adult ; lower jaw pointed anteriorly.

Jaws equal anteriorly ( $\sigma^{\circ}$ 身) or the lower the shorter ( f ); interorbital region convex
3. villughbii.

Jaws equal anteriorly (of 와) or the lower projecting ( $\mathbf{\sigma}^{\circ}$ ) ; interorbital region flat
4. perisiz.

## 1. Salvelinus killinensis.

Salmo killinensis, (iunth. Proc. Zorl. Suc. 1-6:5, p. Gra. pl. xl., and Cat. Fish. ri. p. 130 (levi(i) ; Lay, Fish. Britain, p. 113, pl. exviii. fig. I (1884).

Depth of boly about 4 in the length, length of head 35 to $4 \frac{1}{4}\left(\delta^{\circ}\right)$ or $4 \frac{1}{3}$ to $4 \frac{4}{5}(9)$. Snout obtuse, with upper profile decurved, as long as or longer than ege, the diameter of which is $4 \frac{1}{2}$ to 6 in the length of head. Interorbital region more or less convex, its width 3 to $3 \frac{1}{3}$ in the length of head. Dentition moderate; lower jaw shorter than the upper ; masillary extending nearly to below the posterior margin of eve or a little berond, its length $2 \frac{1}{4}$ to $2 \frac{1}{2}(\zeta)$ or $2 \frac{2}{5}$ to $2 \frac{3}{4}(\xi)$ in the length of head; lower jaw rounded anteriurly, its length $1 \frac{1}{2}$ to $1 \frac{3}{5}$ ( $)^{\text {) }}$ ) or 13 to $1_{4}^{3}(0)$ in the length of head. 9 to 12 branchiostegals. 14 to 16 short gill-rakers on the lower part of anterior arch. 182 to 215 scales in a longitulinal series. Dorsal with 9 to 11 branched rays, its orizin nearer to the tip of snout than the base of caudal, the longest ray $\frac{3}{5}$ to $\frac{3}{4}$ the length of head. Anal with 8 or 9 branched rays. Pectoral from $\frac{3}{4}$ to as long as the head, extending $\frac{5}{8}$ to $\frac{3}{4}$ ( $ठ$ ) or $\frac{1}{2}$ to $\frac{3}{5}(\%)$ of the distance from its base to the base of pelvics. Least depth of caudal peduncle $1 \frac{1}{5}$ to $1 \frac{1}{2}$ in its length and $\frac{9}{5}$ to $\frac{1}{2}$ the length of head. Back and sides plumbeous, belly
silvery or yellowish; small pale spots on the sides; fins dusky, the lower ones with pale anterior edges.

Loch Killin, Inverress-shire.
Several specimens, 200 to 350 mm . in total length, types of the species.

## 2. Salvelinus struanensis.

Salmo struanensis, Gibson-Maitland, Field, 1881, p. 516.
Depth of body 4 to 5 in the length, length of head $3 \frac{8}{3}$ to $4 \frac{1}{5}$. Snout obtuse, with upper profile decurved, nearly as long as or a little longer than eye, the diameter of which is 4 to $4 \frac{1}{2}$ in the length of head. Interorbital region nearly flat, its width $3 \frac{2}{3}$ to 4 in the length of head. Dentition feeble or moderate; lower jaw shorter than and included within the upper; maxillary extending to below the posterior part of eye, its length $24 \frac{5}{5}$ in the length of head; lower jaw rounded anteriorly, its length $1 \frac{3}{4}$ to $1 \frac{5}{6}$ in the length of head. 10 branchiostegals, 13 or 14 short gill-rakers on the lower part of anterior arch. 158 to 180 scales in a longitudinal series.

Fig. 1.

a. Salvelinus struanensis. b. S. inframundus. ots, natural size,

Dorsal with 9 branched rays, its origin nearly equidistant from the tip of smout and the base of caudal, the longest ray $\frac{2}{3}$ to $\frac{3}{4}$ the length of head. Anal with 8 branched rays. Pectoral $\frac{3}{4}$ to $\frac{7}{8}$ the length of head, extending $\frac{2}{3}$ to $\frac{3}{4}(\Omega)$ or a little less than $\frac{2}{3}$ ( $q$ ) of the distance from its base to the base of pelvics. Least depth of caudal peduncle $1 \frac{1}{2}$ to $1 \frac{3}{4}$ in its length and $\frac{1}{3}$ to $\frac{2}{5}$ the length of head.

Hab. Loch Rannoch, Perthshire.
Four specimens, three males and a female, 175 to 210 mm . in total length, including the types of the species.

## 3. Salvelinus willughbii.

Sulmn willughbii, riünth. Proc. Zonl. Suc. 1812, P. 4f, Yl. V., and ('at. F'ish. vi. p. 131 (181j6) ; Day, Fish. Britain, ii. p. 113, pl. cxvii. fig. 2 (1884).
Depth of body $3 \frac{3}{4}$ to 5 in the length, length of head 4 to $4 \frac{1}{4}$ ( ठ) or $4 \frac{1}{4}$ to $4 \frac{2}{3}$ ( $q$ ). Snout conical ( ठ) or somewhat obtuse ( $q$ ), as long as or longer than eye, the diameter of which is $4 \frac{1}{3}$ to 6 in the lensth of head. Interorbital region: convex, its width 3 to $3 \frac{2}{3}$ in the length of heard. Dentition moderate ; jaws equal anterionly or the lower jaw a little shorter than the uper ( ? ) ; maxillary extenling to below the posterior margin of pupil (young) or beyond the eye (alult ठ), its length $2 \frac{1}{2}$ to $\frac{25}{5}$ in the length of hearl; lower jaw pointed anteriorly, its length $\frac{2}{3}$ (adult d) oir less than $\frac{2}{3}$ of the length of head. 9 th 12 branchiotiogals. 11 to 16 moderately long gill-rakers on the lower part of anterion arch. 160 to 194 scales in a longitulinal series. I) msal with 8 or 9 branched rays, its origin maner to the tip of snout than the base of cautal, the longest ray $\frac{1}{2}$ to $\frac{2}{5}$ thes length of head. Anal with 7 to 9 hanchol rays. Pectoral $\frac{2}{5}$ to $\frac{7}{8}$ the length of head, extending $\frac{3}{3}$ to $\frac{3}{4}(\delta)$ or $\frac{1}{2}$ to $\frac{2}{3}$ (?) of the distance from its hase to the base of pelvics. Least depth of caudal peduncle $1 \frac{1}{2}$ to 2 in its lengeth and from $\frac{1}{3}$ to more than of the lengh of head. (ireenish or h,hish above, silvery or orange helow ; back and sides with orange spots; dursal and caulal lusky; lower fins more or less red, the pelvics and anal with pale anterior edges.

Windermere.
Sisteen specimens, 160 to 290 mm . in total lengthi, including the types of the species.

## 4. Salvelinus perisii.

Salmo cambricus (non Donor.), Giunth. Proc. Zool. Soc. 185j, p. 49, pl. ri.
Salmo perisii, Günth. Ann. \& Mag. Nat. Hi-t. xr. 1ation, p. is. and Cat. Fïh. ri. p. 133 (1=66) ; Day, Fish. Brituin, p. 112, pl. cxis. fig. 2 (1884).

Depth of body $4-5$ in the length, length of heal $3 \frac{1}{-1}$ ( $\mathbf{\sigma}^{\text {) }}$ or $4 \frac{1}{4}-4 \frac{1}{2}(\circ)$. Snout conical, pointel. as long as or long r than eye, the diameter of which is $4 \frac{1}{3}-5$ in the lengeth of head Interorbital region flat, its width $3 \frac{1}{2}-3 \frac{3}{4}$ in length of head. Dentition rather strong; jaws equal anteriorly ( d of ) or the lower projecting ( $\delta$ ); maxillary extending hearly to belom the posterior margin of eve or a little levondi, its

lower jaw pointed anteriorly, its length $1 \frac{3}{7}-1 \frac{1}{2}$ ( J ) or $^{2} \frac{1}{2}-1 \frac{3}{3}$ ( 7 ) in the length of head. $10-11$ branchiostegals. $13-16$ slender gill-rakers on the lower part of anterior arch. 156188 scales in a longitudinal series. Dorsal with 9 or 10 branched rays, its origin a little nearer to the tip of snout than the base of caudal, the longest ray $:-\frac{2}{3}$ the length of head. Anal with 8 or 9 branched rays. Pecteral $\frac{3}{4}-\frac{8}{5}$ the length of head, extending $\frac{2}{3}$ to more than $\frac{3}{2}\left(\delta^{\top}\right)$ or $\frac{3}{3}(q)$ of the distance from its base to the base of pelvics. Least depth of caudal peduncle $1 \frac{1}{2}-2$ in its length and $\frac{1}{3}-\frac{2}{5}$ the length of head. Dark greenish above, silvery or orange below; sides with orange spots; fins more or less dusky, the lower fins tinged withs orange and with pale anterior margins.

Lakes of Llanberis, Carnarvonshire, North Wales.
The above description is based on the types of the species, twelve examples, $180-235 \mathrm{~mm}$. in total length.

The following five species of Char are so distinct from each other and from the ones described above that I Lave little hesitation in describing them as new.

## 1. Salvelinus gracillimus, sp. n.

Depth of boly $5 \frac{1}{2}$ to $6 \frac{1}{2}$ in the length, length of head 4 to $4 \frac{1}{2}$. Snout obtuse, as ling as or a little longer than eye, the diameter of which is $4 \frac{1}{4}$ to 5 in the length of head. Interorbital region nearly flat, its width $3 \frac{1}{2}$ in the length of head. Dentition moderate ; jaws equal anteriorly; maxillary

## Fig. 2.

a. Salvelinus gracillimus, b. S. lonsdalii. ōs, natural size.
extending to below the posterior part of eye, its length $2 \frac{2}{5}$ to $2 \frac{5}{6}$ in the length of head; lower jaw somewhat pointed anteriorly, its length from less than $\frac{3}{5}$ to $\frac{2}{3}$ the length of head. 9 branchiostegals. 13 or 14 moderately elongate gill-rakers
on the lower part of anterior arch. 164 to 186 scales in a longitudinal series. Dorsal with 8 or 9 branched rays, its origin nearer to the tip of snout than the base of candal, the longest ray about $\frac{3}{5}$ the length of head. Anal with 7 or 8 branched rays. Pectoral $\frac{3}{4}$ to $\frac{7}{8}$ the length of head, extendiner ${ }_{5}^{3}$ to $\frac{3}{4}$ of the distance from its hase to the base of pelvics. Least depth of caulal perhuncle $1 \frac{4}{5}$ to $2 \frac{1}{3}$ in its length and $\frac{1}{3}$ the length of head. Back and sides, with dorsal and caudal fins, bluish grey; belly silvery or orange; orange spots on the sides.

Hab. Loch of Girlsta, Tingwall, Shetlands.
Four male specimens, 150 to 200 mm . in total length, three of them recently presented by Mr. J. S. 'Tulloch, who tells me that Girlsta is the only char loch in the Shetlands.

## 2. Salvelinus inframundus, sp. n.

Depth of body $4 \frac{1}{2}$ to $4 \frac{2}{3}$ in the length, length of head $4 \frac{1}{4}$ to $4 \frac{1}{2}$. Snout obtuse, with upper profile decurved thronghout, a little longer than ere, the diameter of which is $5 \frac{1}{4}$ to $5 \frac{1}{2}$ in the length of head. Interorbital region convex, its width $3 \frac{1}{3}$ to $3 \frac{1}{2}$ in the length of head. Dentition feeble; lower jaw shorter than and included within the upper; maxillary extending nearly to below the posterior margin of eye, its length 238 in the length of head; lower jaw rounded anteriorly, its length $1 \frac{3}{4}$ to $1 \frac{4}{5}$ in the length of head. 10 or 11 branchinstegals. 13 or 14 rather short gill-rakers on the lower part of anterior arch. 178 to 195 scales in a longitudinal series. Dursal with 9 branched rays, its origin nearer to the tip of snout than the base of caudal, the longest ray ? the length of head. Anal with S or 9 branched rays. Pectoral a little more than $\frac{2}{3}$ the length of head, extending $\frac{1}{2}$ of the distance from its base to the base of pelvics. Least depth of caudal peduncle 2 in its length and $\frac{1}{3}$ to $\frac{3}{8}$ the length of head. 59 vertebres. Colour in spirits: brownish on back and sides, paler below; some small pale spots on the sides; dorsal and caudal fins dusky.

This description is based on two male specimens, 185 and 195 mm . in total length, from Hellyal Lake, Hoy Island, Orkneys, presented by Dr. 'Irail in 1862.

During the last few years Mr. Whlliam Corran has marle attempts to get more examples of this interesting form, but without success. I have it on his authority that char are not found in any other lakes in the Orkneys. IIr. T. Middlemore, who owns the lake, has also made unsuccessful efforts to catch some char; none have been captured since h. has been the proprietor, and he believes they are extinct.

## 3. Salvelinus maxillaris, sp. n.

Depth of body $4 \frac{1}{4}$ to $5 \frac{1}{3}$ in the length, length of head $3_{5}^{4}$ to $4 \frac{1}{5}$ ( $\sigma^{2}$ ) or $4 \frac{1}{3}$ to $4 \frac{3}{5}$ ( $q$ ). Snout subconical ( $\sigma^{\star}$ ) or obtuse, with upper profile decurved (of), longer than eye, the diameter of which is $5 \frac{1}{2}$ to $6 \frac{2}{3}$ in the length of head. Interorbital region convex, its width $3 \frac{1}{3}$ to $3 \frac{2}{3}$ in the length of head. Dentition moderate; jaws equal anteriorly ( $0^{\text {a }}$ ) or the lower a little shorter than the upper (q); maxillary extending to below the posterior margin of eye ( $\rho$ ) or beyond ( $\delta$ ), its length $2 \frac{1}{4}$ to $2 \frac{1}{2}$ ( $\delta$ ) or $2 \frac{1}{2}$ to $2 \frac{2}{3}$ ( $q$ ) in the length of head; lower jaw obtusely pointed anteriorly, its length $\frac{2}{3}$ to more than $\frac{3}{4}\left(d^{2}\right)$ or $\frac{2}{3}$ or less ( 8 ) of the length of head. 10 or 11 branchiostegals. 14 or 15 rather slemter gill-rakers on the lower part of anterior arch. 168 to 186 seales in a longitudinal series. Dorsal with 9 to 11 branched rays, its origin equidistant from the tip of snout and the base

Fig. 3.

Salvelinus maxillaris, $\frac{3}{4}$ natural size.
of caudal or a little nearer the former, the longest ray $\frac{1}{2}$ to $\frac{2}{3}$ the length of head. Anal with 8 to 10 branched rays. Pectoral $\frac{2}{3}$ to $\stackrel{5}{6}_{6}$ the length of head, extending $\frac{1}{2}$ to $\frac{2}{3}\left(\delta^{2}\right)$ or $\frac{1}{2}$ or a little less ( $q$ ) of the distance from its base to the base of pelvics. Least depth of caudal peduncle $1 \frac{1}{2}$ to 2 in its length and about $\frac{1}{3}$ the length of head. 64 vertebre. Back and sides, with the dorsal and caudal fins, plumbeous; belly brilliant orange; small orange spots on the sides, mostly below the lateral line; pectoral greenish, with a red margin; pelvics and anal reddish, with a white anterior edge ; caudal with an orange margin.

Hab. Loch near Ben Hope, Sutherlandshire.
Eleven specimens, 210 to 280 mm . in total length, one
presented by Mr. R. Etheridge in 1873 and the nthers recently sent to me by Mr. John Murray at the request of Dr. F. Penrose.

## 4. Salvelinus mallochi, sp. 11 .

Depthinf body $4 \frac{1}{2}$ in the length, length of head $4 \frac{1}{3}$ to $4 \frac{1}{2}$ (3) or 43 to $4 \frac{4}{5}$ ( 8 ). Sout obtuse, Inger than eye, the diameter of which is $5 \frac{1}{2}$ to 6 in the length of head. Interorbital remion convex, its width 3 to $3 \bar{j}_{5}$ in the longth of hear. Hentition moderate; lower jaw a liftle shorter than the upper ; maxillary extending nearly to below the posterin marein of eye or a little beyond, its length $2 \frac{2}{5}$ to $2 \frac{2}{5}$ in the length of head; lower jaw obtusely pointel anterionly, it - length $\frac{3}{3}$ to $\frac{2}{3}$ of the length of head. 9 to 11 hranchostegale. $1: 3$ or 14

Fig. 4.

rather slender cill-rakers on the lower part of anterior arch. 1 se to 200 seales in a longitulinal series. I) rsal with 10 hanched rays, its origin nearer to the tip of smont than the hase of caudal, the longest ray $\frac{1}{2}$ to $\frac{3}{3}$ the length of hear. Anal with $S$ or 9 branched rays. Pectoral $\frac{2}{5}$ to 5 the length of head, extending $\frac{1}{2}$ to $\frac{3}{5}(\sigma)$ or a little less than $\frac{1}{2}(f)$ of the distance from its base to the Lase of pelvics. Least depth of caudal peduncle 14 to 2 in its lencth an $\frac{1}{3}$ to $\frac{2}{5}$ the length of head. Slate-coloured above, whitish tinged is ith orange below; numerous pale spots covering the back as well as the sides.

Hab. Loch Scourie, Sutherlandshire.
Four specimens, 220 to 290 mm . in total length.
I have named this species after the donor, MIr. P. D. Malloch, the well-known naturalist of Perth.

## 5. Salvelinus lonsdalii, sp.n.

Dupth of body $4 \frac{1}{2}$ to 5 in the length, leugth of head 4 ( $\delta$ ) or $4 \frac{1}{2}(\%)$. Snout subconical, longer than eye, the diameter of which is $4 \frac{2}{5}$ to $5 \frac{1}{3}$ in the length of head. Interorbital region slightly convex, its width $3 \frac{1}{4}$ to $3 \frac{1}{2}$ in the length of head. Dentition moderate; jaws equal anteriorly ; maxillary extending to below the posterior margin of pupil ( $q$ ) or b yond $\left(\sigma^{*}\right)$, its length $2 \frac{1}{2}\left(\sigma^{*}\right)$ or $2 \frac{2}{3}(q)$ in the length of heal ; lower jaw pointed anteriorly, its length more than ( $\delta^{\pi}$ ) or a little less than $\frac{2}{3}$ ( $f$ ) of the length of head. 9 to 11 branchiostegals. 13 slenter gill-rakers on the lower part of anterior arch. 166 to 182 seales in a longitudinal series. Dursal with 9 branched rays, its origin a little nearer to the tip of snout than the base of caudal, the longest ray $\frac{2}{3}$ to $\frac{3}{4}$ the length of head. Anal with 8 branched rays. Pectoral ${ }_{5}$ to $\frac{7}{8}$ the length of head, extending $\frac{4}{5}$ ( $\delta$ ) or nearly $\frac{2}{3}$ ( $q$ ) of the distance from its base to the base of pelvics. Least depth of caudal peduncle about $1 \frac{3}{4}$ in its length and about $\frac{2}{5}$ the length of head. Bluish black above, orange below"; numerous orange spots on the sides ; dorsal and caudal dusky.

Haweswater.
Two sp cimens, 170 mm . in total length, presented by the Earl of Lonstale, after whom I have named the species.
'This species is distinguished from S. willuyhbii especially by the much longer lower jaw and bears a great resemblance in s. perisii, from which it differs in the smaller eye and in having the dursal fin a little higher and the pecturals rather longer.

Day (Fish. Britain, ii. p. 116) quotes J. Davy to the effect that the Char of Haweswater is a small and slender tish compared with that of Windermere. Sir H. Davy's figures ('Salmonia,' p. 260, 1851) show well the main difference hetween the two forms. Mr. W. H. Parkin writes me that the Char caught in Haweswater hardly vary at all in size.

Char from other British localities in the National Cullection include some forms which seem to be practically identical with one or other of the species described above, and others which may prove to be sufficiently different to be described later on as distinct species ; in some cases more specimens are wanted in order to determine how far the differences observed may Le constant ; in other cases I have seen enough examples to dotermine pretty accurately the normal variation of the char in certain lochs, but these forms differ so slightly from their nearest allios that 1 do not venture to deseribe them unt

I have examined specimens from intermeliate lucalitis. There are still a number of lochs in Sutherlandshire, ionsshire, and Inverness-shire which contain Char, but from which I have not yet seen any.

In the following list of specimens I have cxamined I give in cach case the number of branched rays in the dorsal fin (D) and in the anal fin (A), the numb $r$ of seales in a longitudinal series (sc.), of branchiostegals ( B), an I of gill-rakers on the lower part of the anterior arch (Gri.).

## (1) Char allied to S. killinensis.

1. Loch Ror, a small loch at the head of Gilen Rny in Inverness-shire; a single specimen ( ठ) , 160 mm . in total length, presented by Mr. II. Cholmendeley Pemeell in $1 \times 62$. D. 7 ; A. 3 ; Sc. 160 ; B. 9 ; Gr. 15 . Head perhaprs a little smaller and scales larger than in th: Killin Cuar, but, considering the variation in the. number of scales in other forms, e. (1. the Loch Loval ('lar, ant our igmoname of the Char of other lochs in Invernes--shire (escept L. Bruath), I cannt yet recognize this form as even a distinct race.

## (2) Char allied to S. willughbii.

1. Coniston Lake; three specimens ( of ) $190 \mathrm{t}, 240 \mathrm{~mm}$. in total length, preeented by ML. J. W. Barratt. D. 9-10; A. 8-9; S'c. $18(i-198$; B. 10-11; Gr. 12-13. Nearly identical with the Windermere Char.
2. Crummock Water; four specimens ( $\delta$ of) 270 to 280 mm . in total length, presented hy Mr. W. H. Marshall. D. $9-10$; A. 8 ; Sc. $160-170$; B. $9-12$; Gr. 12-14. Iractically identical with the Windermere Char.

These examples were in splendid condition, and when they arrived I drew up the following description of their colora-tion:-"Back and sides bluish, with silvery reflections and with numerous pink spots every where ; faint traces of 9-12 parr-manks; lower parts red; snout, upper part of head, and sometimes the maxillary blackish; luwer jaw, branchiostegals, and thorax white; cheeks and opercles silvery, with shades of green, blue, or pink; iris golden, pupil black ; dursal and caudal fins blackish, with or without pale spots at the base ; pectoral dusky, tinged with red, sometimes with the upper ray whitish; pelvics and anal similar, but redder and with strongly marked white anterior edges."
3. Loch Gransoch in Kirkeudbrightshive ; eight specimens ( $\delta$ of ), $160-230 \mathrm{~mm}$. in total length, three presented
by Mr. Robert Service and five by Mr. G. R. Murray. D. $9-10$; A. $7-8$; Sc. $15 \pm-176$; B. $8-11$; Gr. 11-13. A race of S. willughliii, assuming adult characters at a smaller size.
4. Loch Dungeon in Kirkcudbrightshire; one specimen ( $\sigma$ ), 160 mm . in total length, received on loan from the Edinburgh Museum. D. 10 ; A. 8; Sc. 180; B. 10 ; Gr. 13. A race of $S$. willnghbii ; lower juw weaker and opercular bones broader than in the Grannoch Char.
5. Locu Donv in Ayrshire ; elevenspecimens (o f ) , 160180 mm . in tutal lenstl!, presented by Mr. R. Servic. D. $8-9$; A. $8-9$; Sc. $146-174$; B. $9-10$; Gr. 12-14. A small race of So willughbi, very similar to the Gramoch Char, usually with mouth larsar, oparcular bones narrower, and paired fins longer than in Windermere Char of this sizs.
6. Loch Butlg in Banffshire; four specimens ( $\delta$ of), $180-220 \mathrm{~mm}$. in total length, presented by Messis F . D. Godman and IV. R. O. (xrant. D. , -10 ; A. 7-9; Sc. 160180 ; B. 9-11; Gr. 14-15.
7. Locif Bruidch in Inverness-shire; ten specimens ( $\delta \mathrm{f}$ ), $175-190$ mon. in total length, presented by Lord Lovat. D. 8-10; A. $7-9$; Sc. $15.5-178$; B. $9-11$; Gr. 1416. A small race of $S$. willughbii ; coloration dark; pelvic axillary scale long.
8. Loch Morie in Ross-shire; one specimen ( ${ }^{\text {® }}$ ), 200 mm . in total length, presented by Mr. H. M. Warrand. D. 9 ; A. 8; Sc. 156 ; B. 10 ; Gr. 16. Similar to the Bruiach Char.
9. Loch Borollan in Sutherlandshire; two specimens ( $\delta^{\sigma}$ ), 150 and 165 mm . in total length, from Dr. F. Day's collection. D. 10 ; A. $\delta$; Sc. 166-172 ; B. 9-10; Gr. 15.
10. Loch Loyal in Sutherlandshire; thirty-eight specimens ( $\delta$ of), $150-200 \mathrm{~mm}$. in total length, presented by Mr. John Murray. D. 8-11; A. 7-9; Sc. 126-178; B. 812 ; Gr. 11-16. A small race of S. witlughbii, according to Mr. Murray never attaining a larger size. The range of variation in the number of scales is most remarkable.
11. Loch Baden in Sutherlandshire ; two specimens (of ), 165 and 185 mm . in total length, presented by Mr. P. D. Malloch. D. $9-10$; A. 8-9; S.c. 145-152; B. 9-10; Gr. 16-17. Head smailer than in the Loch Loyal Char,

Anr. \& May. N. Hist. Ser. 8. Vol. iii.
12. Loch Calder in Caithness; a sluffed specimen of 230 mm ., received on loan from the Elinburgh Musenm. D. 9 ; A. 8 ; Sc. 166 . Apparently identical with the Baden Char.
13. Nortir Uist ; a single specimen ( ठ), 260 mm . in total length, presented by Sir A. J. Camphell Orde. D. 10; A. 9 ; Sc. 175 ; B. 10 ; Gr. 14 . A short-headed form of S. willuglibii; silvery, back bluish.

## (3) Char allied to S. perisii.

1. Cose-y-Gedawl in Merioneth-hire; four specimens, $125-150 \mathrm{~mm}$. in total length, from Yarell's collection. D. $9-10$; A. $8-9$; Sc. $141-166$; B. $9-10$; Gr. $14-16$. Probably not distinct from the Llanberis Char.

## (4) Char allied to S. maxillaris.

1. Locir Stack in Sutherlandshire ; two specimens (of), 215 and 220 mm . in total length. D. $9 ;$ A.s-9; Sc. $182-$ 114; B. 9-10; Gr. 14-15. Nearly identical with the Char from Ben Hope, but paired fins a little longer than in female specimens from that locality, the pectorals extending $\frac{3}{3}$ of the distance from their base to the pelvics.
XVI.-On some new and rave Entomostraca from the Scotlish Seas. By Thomas Scott, LL.D., F.L.S.
[Plates II.-IV.]
The Entomostraca described here were obtained in collections made from time to time by the Fishery Steamer 'Goldseeker ' while carrying on work in comexion with the international scheme for the investigation of the North Sea and adjacent waters, and under the directions of Professor d'Arcy IF. Thompson, (..B., F.L.S., the representative for Scotland on the International Committee.

For permission to publish these notes I am indebted to Professor Thompson.

## Calanoida.

Xanthocalanus tenuiremis, sp.n. (c) .
(Pl. II. figs. 1-7.)
A suecimen of a male Santhocalemus was oltained in a
gathering of Crustacea from 1140 metres, collected by the 'Goldseeker' at Station 53, about 70 or 80 miles north by west of the Butt of Lewis ( $5 .{ }^{\circ} 36^{\prime} \mathrm{N}$. lat., $7^{\circ} \mathrm{W}$. long.). As this specimen represents what may be either an undescribed species or the undescribed male of some species the female of which is already known, the following particulars concerning it may not be without interest.

The specimen has a general resemblance to $X r n t h o c a \neq u n s$ borealis, G. O. Sars, and measures about 2.5 mm . in length (fig. 1).

Rostrum of moderate size and bifurcate, the segments are elongate, stout at the base, but taper towards the pointed extremities (fig. $1 a$ ).

Antennules wanting ; the antennæ, which are also slightly imperfect, resemble those of $X$. borealis (fig. 2).

Mandibles stout, with a strong masticatory part; the tonth on the inner aspect of the biting-edge is broal and massive and projects somewhat beyond the others (fig. 3) ; the mandible-palp, which is stout, is slightly imperfect (fig. 4).

First maxillipeds stout, each of them armed with two or three long and stout setiferous spines and a number of elongated plumose bristles, and there is also present the characteristic fascicle of sensory filaments (fig. 5).

The four pairs of swimming-feet were all more or less imperfect : fig. 6 represents what remains of the fourth pair.

The fifth pair has the left leg greatly elongated and slender, so that it is only a little shorter than the entire lenorth of the cephalothorax. The basal joint of this leg is moderately stout and rather longer than the right leg; the next three joints are subequal and considerably longer than the basal joint, and each is more slender than the joint that precedes it ; the end joint is very small and terminates in a bifurcated process, as shown in the enlarged figure (fig. $7 \alpha$ ). The right leg is short and rudimentary, and appears to be composed of three (or four) joints (fig. 7).

Remarks.-This species appears to be a true Xenthocalanus. The structure of the antennæ, and especially of the first maxillipeds and of the fifth pair of thoracic legs, agrees with the characters common to the species of this genus. The first maxillipeds are each furnished with a terminal fascicle of slender sensory filaments as in $X$. borealis, but with no sheaf-like bundles as in Amallophora; they are also armed with two strong, elongated, and more or less setiferous spines, besides a number of plumose setæ. Further, in the fifth pair of thoracic feet the right leg is very short, while the left is slender and elongated as in $X$. borcalis. In the species
mow described, however, the structure of the clongated loft leg differs from that of any of the others known to me in the proportional lengths of the varims joints and in the peculiar armature of the terminal one. The mutilated condition of the only specimen observed prevents a more detailed acoomit being given, l, ut the characters available are, taken together, suflicient to di-tinguish this form from its confreres.

## Amallophora claviger *, sp. n. (Pl. III. figs. 1-11; Pl. IV. figs. 13-17.)

Cephalothorax moleratoly chongatel; forehead romoded; rontrum bïmeate, with modemately long tapering branches; ahomen compasid of tive sngments. candal rami vey shont. Length about 4.7 mm . (Pl. 111. 6ig. 1).

Antemules rather lomger than the cephaloth nax, molerately slender and composed of twenty-five juints ; first and secoml joints somewhat dilated, the hext four small, suberpal, the sixth to the twelfth more or less coalmesent, thirteenth and fourternth small, the fiftrentla to the ninetecnth rather longer than the preseding two joints or those that finlow, as in the formula, which shows approximately the promertional lengths of the various joints:-

Number of the joints $\ldots \ldots \ldots$...... $1 \quad 2 \quad 3 \quad 4 \quad 5 \quad 67889101112$
Proportional leugths of same .. 17.12 .7 .8 .7 .8 . 38.

See also the drawing (PI. III. fig. 3).
Antemax small, imer branch much shorter than the outer (Pl. III. fig. 4).

Mandibles small, narrow, elongated, distal end somewhat comstricted, biting end obsiquely truncated and armed with small ilenticies ; mandible-palpsmall (II. III. fig.j; Pl. IV. fig. 13).
first maxilifred small, fumished with a dense fascicle of sensory filamerts and a number of sete as shown in the drawing ( ${ }^{2}$ I. III. fig. (6). Recond maxillipeds also small, elongated, and sparingly setiferons (Pl. Ill. fig. 7).

The fiur pairs of swimming-fent are somewhat similar to those in Xanthocrlamus bursalis, (x. O. Sars. The fitth pair has also a general remblance to those of the same species,

[^15]but there are structural differences which at once distinguish this 'Goldseeker' Calanoid from Amalt, phora typien, T. Scott, which it somewhat resembles. 'The left leg of the fifth pair is elongated and slender, as in the fifth pair of A. typich, and the first and second joints are moklerately stout, but the second joint is about one and a half times lunger than the first, while the first and second are together rather less than half the entire length of the leg; the third joint is very slender and about one and a half times longer than the second; the fourth joint is scarcely half as long as the third, and becomes somewhat dilated towards the distal end ; the distal half of this juint is hollow on the exterion edge and assumes a spoon-like form to receive the end joint, which is folded back upon the fourth and is greatly attenuated towards the distal extremity, and terminates in a minute hook; the end joint bears several minute seta on its inner edge, and a small seta projects from the end of the fourth joint (I'l. IV. figs. 15-17). The right branch is very short and reaches slightly beyond the first joint of the left branch; it consists of tive joints, but the three end ones are very small (Pl. IV. fig. 15).

Hab. 'Goldseeker' Station 53 (lat. $59^{\circ} 36$ 'N., long. $7^{\circ}$ W.); depth 1140 metres, August 17 th, 1908. A few male specimens only observed.

Remarks.-Though the form here described approaches somewhat closely to Amallophora typica, the structure of the fifth pair of thoracic legs is decidedly different; the left leg differs not only in the proportional lengths of all the joints, but also in the form and armature of the end joint.

It may be remembered that Amallophora typica has beens relegated to the genus Xanthocalanus ly Dr. Giesbrecht, but though it agrees with that genus in some particulars, as, for example, in the structure of the fith pair of thoracic legs, it differs in other respects, and notably in the armature of the first masillipeds, which possesses a character distinct from that observed in described species of that genus. In the typical Xanthocalamus (N. agilis, (iiesb.) the first maxillpeds are provided with a number of slender sensory filaments, but they have no large and conspicuous sheaf-like bundle of delicate threads inextricably mixed together as in Amallophora. 'This genus I therefore retain for the two species mentioned here, viz. Amallophora typica and A. claviger.

## Neoscolecithrix kohleri, Canu.

1896. Neoscolecithrix koehleri, Canu, Ann. Univ. Lyon, vol. xxvi. p. 426, pl. xviii. figs. 1-9.
1897. Sonlecithrix Kahleri, Giesbrecht, Das Tierreich, 6 Lief. (Coplepoda) p. 46.
190テ. Oothrie bidentata, Farran, Ann. I p. Fi-h. Ireland, 1902-03, pt. ii. App. ii. (1905) p. 42, pl. x. figs. 15-18, pl. xi. figs. 1-10.
This appears to be a true deep-water species; it was moderately common in two of the 'Gultseeker' gatherings, one from 1140, the other from 1100 metres, colleeted in lat. $59^{\circ} 36^{\prime} \mathrm{N} .$, loner. $7^{\circ} \mathrm{W}$., and lat. $59^{\circ} 25^{\prime} \mathrm{N} .$, long. $7^{\circ} 33^{\prime} \mathrm{W}$., in August 1907.

Having had the privilege of examining well-developed specimens of both the male and female of this species. I am convinced that Uothrix bidentuta is identical with Seoscolecilhix kobliteri, and also that the sprecies is mot a true Scolecithric', and that Camu's mane should therefore the restored.

## Genus Pseudotharybis, nov.

Resembling Therylis, (G. O. Sars, in general appeanance. Female antemules composed of twenty-four joints. Anteme with the imer ramus considerably shorter than the onter. Mandiibles with the biting edge truncated and armed with stout tecth. Maxillie somewhat expanded, masticatory love broally truncate and fumished with several setiterous spines. F゙irst maxillijeds whout sensory filaments. otherwise nearly as in Tharylis. Second maxillipeds und swimming-feet also nearly as in that genus. Last pair of legs triariculate. end joint with a spinitorm extremity, and with two stout spines on the outer margin.

> Pseudotharybis zetlandicus, sp. n., $f$. (Pl. II. figs. $8-13 ;$ Pl. III. figs. 12-18.)

Body rubust; forehead broadly rounded; rostrum short, bifurcated, furea short, broadly triangular, somewhat divaricated, and with a moderately wile space between them (Pl. II. fig. 9). The first cephaluthoracic segment more than halt the length of the cephaluthorax; the lateral angles of the last segment are produced into sharp tooth-like pro. cesses, which are slightly divaricate. Abdumen short, with short furcal rami (Pl. II. fig. 8).

Length 3.8 mm .
Antemules ( P l. II. fig. 10) somewhat shorter than the cephalothorax and composed of twenty-tour joints, the proportional lengeths of which are nearly as in the furmula : $\begin{array}{lllllllllllll}\text { Nunber of the joints } . \ldots \ldots . . & 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 & 10 & 11\end{array}$ Proportional length of ditto.. $20,16,8,8,8,8,9,13,8,8,8$.

$$
\frac{12}{12} 13 \quad 14 \quad 15: 16 \quad 17 \quad 18 \quad 19 \quad 20 \quad 21 \quad 22 \quad 23 \quad 24
$$

Antenne not very elongated, moderately stont, imner ramus considerably shorter than the outer (Pl. III. fig, 12).
'The mandibles, which somewhat resemble those of the species last described, have a strongly toothed masticatory edge (Pl. II. fig. 11).

The three inner marginal lobes of the first maxilliperls are each furnished with two apical setæ, coarsely plumose and elongated, and a shorter reflexed seta; the next two lobes terminate in long slender and slightly curved spines (Pl. III. fig. 13).

The five terminal joints of the second maxillipeds are short and furnished with a number of rather slender bristles (Pl. III. fig. 14).
'The swimming-feet are somewhat similar in structure to those of the species previously described. The first pair are moderately stout, but much smaller than the next pair, and the spines on the outer distal angles of the three joints of the outer ramus are not very strong (Pl. III. fig. 15). The outer ramus of the second pair is moderately elongate and broadly lamelliform ; the marginal spines are strong, rather long and setiferous, but the apical spine is comparatively short and stout and coarsely serrated on the outer edge (Pl.III. fig. 16). The outer rami of the third and fourth pairs are narrower than that of the second, and the marginal spines more slender; the terminal spine is moderately stout and coarsely serrated on the outer edge, the number of teeth being about eighteen. The integument of the inner branches is covered more or less with mmute denticles (Pl. III. fig. 17).

The fifth pair of feet are small and symmetrical, each consists of a single three-jointed branch; the third joint, which is rather longer than either of the other two, is produced anteriorly into a moderately long spine and is armed with two other spines, one near the proximal end of the outer margin and the others on the outer distal angle (PI. III. fig. 18). The first and second joints are without conspicuous armature.

Hab. 'Goldseeker' Station 53 (lat. $59^{\circ} 36^{\prime}$ N., long. $7^{\circ}$ W.), 1140 metres deep, collected in August 1907. One or two specimens only obtained; no male observed.

In the same gathering with the species just described were others already known to science, such as Arietellus plumifer, G. O. Sars, a highly coloured form with densely plumose tail-seta; Chirundina streetsi, Giesbrecht, described from specimens collected off the west coast of North America in lat. $35^{\circ}$ N., long. $125^{\circ} \mathrm{W}$. ; Candecia norvegica, Boeck; Guetanus latifions, (i. O. Sars; Meynectalames lonyicornis
(G. O. Surs) ; Motritice priuceps, (ibeshrecht; and various others to be described later.

## Halocypridæ.

Genus Euconchecta, G. W. Müller, 1890.

> Euconchoecia d'arcy-thompsoni, sp. ". (Pl. III. fig. 19 ; Pl. IV. figs. l-12.)

Shell, seen from the sile, oblons; length se uredy equal to twice the wilth. Dusal marein nearly straight, each valve tominating porterion! in a small pointel promes, while in fromt the rustral prijection, which is distinctly hifif, is bennded benmath ly a denp sime, as shown in the drawing (Pl. IV. figs. 1 © 2 ) ; ventral marein marly parall I with the dowsal and slightly but evenly munded; posterior emd subquadramgular; anterior end holdly cursed ; shell-gland near the posterodorsal angle, as shown in the drawing (I'l. IV. fig. 2).

Longth of the shell represented by the drawing about $4 \cdot 7 \mathrm{~mm}$.

The antemmles are each provided at the apex with a dense fascicle of very slender bristles and whith three (or four) seter ; two of these sita are long and slember, but of unequal length,

Anten:e similar to those in Eiuconchucin cherchier, G. W. Miiller; the scomdary branch on the right side is armed with a strong lowk (Pl. IV. fig. fi), that on the left sile is also provided with a hook, lut it is much smatier than the other.

Man libular fost nearly as in Concluciu remens, the masticatory part armed with sceveral smail teeth (I'I. IV. fi \&. 7).

Finst iont slender and monleratrly clongated, end juint very small, with one long and moderately stwat seta and two other smaller ones (Pl. IV. fir, 3). Second fuot considerably shorter than the first (Pl, IV, fig. 10).

Caudal lamina somewhat similar to that of $E$. chirrchice, Miilier, except that it is armed with eight spines; the principal spine exhilnts the same mumber of articulations as that of the caudal lamina in the species named. Copulatury organ rather narrow and elongatel (Pi. IV. figs. 11 \& 12).

The femaie dies 1.0 d differ ereatiy trom the male, except that the rostral h:ool-like projection at the anterionent of the shell is not bifid as in the male (P'l. IV. lig. 4) and that t..e ancessory branch of the antema has no homatike appendage
(Pl. III. fig. 19). In the female dissected the nva were numerous and small. The shell in both sexes ornamented with faint delicate reticulations. 'The groups of ghands situate 1 near the postero-dorsal angles of each of the two valves, as indicated in the drawing ( I'1. IV. fig. 2), are quite distinct.

Hab。'Goldseeker' Station 53, lat. $59^{\circ} 36^{\prime} \mathrm{N}$., long. $7^{\circ} \mathrm{W}$. , 1140) metres deep, collected in August 1907. Two adult males and one female, and other two smaller specimens which appear to be young males.

Remarks.-The occurrence of this Euconchecciuat Station 53 appears to be of interest, as it differs so much in size and in other respects from E. chierchive, G. W. Müller, the only other species of the genus. E. chierchice was described from specimens collected by Dr. Chierchia off the Brazilian coast in lat. $19^{\circ} \mathrm{s}$. and long. $39^{\circ} \mathrm{W}$.; these specimens measured about 1.2 mm . in length \%. The same species was described and figured in the Report on collections made by John Rattray in the Gulf of Guinea, under the name of Inctocypris aculeata; the size of the specimens from these collections was about $1 \mathrm{~mm} . \dagger$ It has also been recorded from (ruz Bay by Dr. G. S. Brady, who gives the size of the male as 1.1 mm . and of the female as $.85 \mathrm{~mm} . \ddagger$ The 'Goldseeker' specimens are thus about four times the size of E. chierchice. Moreover, in both the adult males the rostral projection of both valves of the shell is distinctly bifid, as shown in the drawing (Pl. IV. fig. 2), but in the shell of the adult female the rostral projection is not bifid. One other point of interest is the large brush of delicate filaments at the apex of the antemmules in both the male and female. The brush at the apex of the antemules in E. chierchice is described by Dr. Brady as consisting "of about twenty setæ." In the 'Goldseeker' specimens the brush consists of several times twenty setæ. I have not counted the number of setæ, for they are so numerous, so delicate, and so crowded together, that the counting of them would be a somewhat serious task-in a small fragment broken off from one of the brushes at least forty setæ were counted.

Owing to the differences mentioned I an inclined to ascribe the 'Goldseeker' specimens to a distinct species, for which I propose the name of Euconchnecia d'arcy-thompsoni, atter Prof. d'Arey W. 'Thompison, C.B., Director of the S'cottish International Investigations.

[^16]Several other interesting ITalocyprians have been obtained in collections made by the 'Goldseeker,' such as Conchocciu elegans, G. O. Sars, C. borealis, G. (). Sars, C'. olitusatu, G. O. Sars, C. daphenoides, Claus, C. imbricata, G. S. Brady, Halocypria (?) globosa, Clans, several species belonging to the Cyprinide, and others which will be described later.

[^17]XVII.-Remarks on some new or little-known Species of Thymidr (lymenoptera). By Rowland E. Turner, F.Z.S., F.E.S.

## Rhagigaster mandibularis, Westw.

This species is quite distinct from the Victrian form of $R$. unicolor, Guér. The male may be distinguished by the tubercle on the mandibles and the absence of the lateral spines at the base of the hypopygium and the female by the much greater breadth of the head.

## Telephoromyia tridentifera, sp. n.

$\delta^{\delta}$. Mandibles tridentate, the outer tooth much the longest. Clypeus short, slightly convex, with an obliquely depressed, concave, semicircular area on the middle of the apical margin, resembling a small but deep emargination, a minute tubercle above the base of the depression. Antennæ further from each other than from the eyes, rather longer than the thorax without the median segment, the apical joints arcuate ; the interantennal prominence bilobed, a delicate median carina on the front almost reaching the anterior ocellus. Pronotum narrower than the head; the mesonetum as long as broad, with two longitudinal sulci on each side, the imer one much the deepest ; scutellum rounded posteriorly; median segment longer than broad, with an obscure median sulcus from the base to the apex. Punctured; most finely and closely on the head, very sparsely on the scutellum, and rather sparsely on the abdomen. First abdominal segment with a sulcus from the base to the middle, the groove between the first and second ventral segments shallow. Abdomen elongate, longer than the head, thorax, and median segment combined, narrowed at the extremities. Epipygium narrowed to the apex and almost pointed, the hypopygium projecting beyond the epipygium, narrow, the sides almost parallel, deeply triangularly emarginate at the apex.

Black; the mandibles broadly in the middle, the clypeus above the depression broadly, two spots between the antenuæ, the inner margin of the eyes broadly as high as the base of the antennæ, a spot at the summit of the eyes, a spot between the posterior ocelli, a line behind the eyes connecting with a crescentic mark on the vertex, the posterior margin of the pronotum, a spot on either side of the pronotum near the middle connecting with the posterior band, an oblique mark on
each side of the prothorax, a broad vertical band strongly emarginate posterionly on the anterion margin of the mesopleure, a large spot above the intemediate coxa, a quadrate spot 0:1 the mesonotum, the terula, the midule of the sentellum inoadly and a spot on cach of the anterior angles, the pmstscutellum, an ohlique line on each side on the modian seament, a transverat band near the apex of the five hasal athlommal soemments narrowly intemupted on all but tiee linst, a large spot on each side of ventral scements $2-4$, and a line on the posterion coxat pale yellow ; legs (exerpt the consp) pale formations ; a yellow line on the anturior temora homath. Wings hyaline, the ratial cell, extembins mone fambly into the cubital cells,
 Second and third cubital colls each receiving a recurent nervure.

## Length 14 mm .

Hab. Mendoza, Argentina; November.
'Type in B.M. ex coll. 'Iurner.
Closely resembling T. rufifers, Guer., in size and colour, but Guerin gives the abdnuen as "simple en anreie," witu" comed not be applied to the pecutiarly shaped hypopygium of this species.

## Spilothynnus lituberculatus, 'I'urn.

Telepheromyia bituberculata, Turn. Trans. Ent. Foc. Londom, p. io (1908), 우.

ס. Mandibles bilentate, the outer tomoth loner and acute, the inner tooth short and broadiy truncate. Ciypeus very narowly emarginate in the midlle of the apical marein, the angles of the emargination prodnced into short spines; a carina from the base produced anterionly into an acute tubercle overarching the hase of the emargination. Antemme inserted a little further from each other than from the eyes, rather short, not longer than the thorax and median segment combined, the apical juints ascuate; the fromt between the antemax bilobed, with a delicate longitulinal carina almost reaching the anterion ocellus. Heat and thoma very closely purctured, the pronutum and scutellum more sparsely, the mesonotum with two longitulinal sulci on each side; median segment as long as broal, with a shallow longitudinal sulcus from the base to the middle, closely punctured. Abjomen elongate, narrow at the base, closely panctured, the segments narrowly depressed and smonth at the apex; the basal segment longer than broad at the apx, with a longitndinal sulcus from the base to beyond the midile. Hypmosium
narrow, only slightly produced beyond the epipygium, rounded at the apex with a very feeble emargination in the middle. The maxillary palpi are rather long, similar to those of Telephoromyia. 'The second recurrent nervure is received at about one-quarter from the base of the third cubital cell.

Black; the mandibles (except at the apex), the clypeus, the anterior margin of the face, a triangular spot between the eyes and the base of the antennæ, an oblique spot on each side above the base of the antennæ, a spot close to the summit of the eyes, a ban l beand the eyes produced more narrowly on the posterior margin of the head and broadly interrupted on the vertex, a smali oblizue spot on each side behind the posterior acelli, the margins of the pronotum broadly united in the midlle, with a small black spot in the middle of the anterior margin, a quadrate spot on the mesonotum, the tegulæ and a curved line above them, a spot on the proplenre and a curved band on the mesopleure, a transverse band on the middle of the scutellum and a spos at each of the anterior angles, the postscutellum, a broad oblique band on each side of the median segment curved ontwardly near the apex, a spot close to the apex of the median segment, a broad band on each of the five basal dorsal segments of the abdomen, narrowly interrupted in the middle on sesments $2-5$, a spot on the first ventral segment, an interupted hand on ventral segments $2-4$ and the coxa and femora beneath yellow ; the two apical abdominal serments, the tibie and the tarsi ferruginous. Wings hyaline, clouded at the apex of the radial cell, nervures black, the stigma ferruginous.

Length 15 mm ., exp. 25 mm .
Hab. Mendoza, Argentina ; February.
The limits of the genera in the Telephoromyia group, including Spilothynnus and Ścotcenc, are not yet well understood, the females being very little known. The present specics has the clypeus tuberculate as in S. letus, but the emargination of the clypeus is much narrower. The mandibles differ in the truncation of the imner tooth from S. leetus and show some approach to Tel. excisa, 'lum., but are not as broad as in that species.

## Pseudelaphroptera haarupi, sp.n.

of. Head twice as broad as long, convex, shining and smooth, with a few very fine scatterell punctures; a short frontal sulcus ; the front almost vertically depressed. Clypeus broadly and shallowly emarginate; the mandibles falcate with a small tubercle on the imer margin close to the base.

Antemæ scarcely longer than the hearl is broad, the scape stout and about half as long as the flagellum. Pronotuin broad, narly twice as broal as long, namower than the head, the median line rather boodly raised, the sides subconcave, the depressions not reaching the finstrior margin. Modian segment and scutellum of almost ergual length, combined scarcely longer than the prono'mm, the whole thorax shining, with a few fine scattered punctures. Abdomen broader than the thorax and much longer than the head, thorax, and median segment combined ; the first and second secments depressed on the apical portion, narrowly at the sides, much more broadly in the middle, the anterior portion smonth and shining, the depressed portion opaque and very finely shagreened; segments $3-i$ smooth and shining, very narrowly and shallowly depressed on the apsical margin; the ventral serments sparsely punctured with a smouth depressed space, broadest in the middle, at the apex of secments $2-1$. Pygidium oblique, twice as long as brom, the sides nearly parallel, the hypopygium projecting heyond the epipygimm, having an exposed surface nearly half as long as the epipygium, rounded at the apex; the epipygium truncate at the apex, with a lone whitish seta on each side near the base. Tarsal ungues bidentate.

Fuscous black; the head and lers dark fusco-ferruginous; the prgidium and antemse finse-ferruginous; the depressed apical portion of the two basal dorsal segments and of ventral segments $2-4$ pale testaceous.

Length $8-9 \mathrm{~mm}$.
Described from two specimens, one of which is apparently not quite mature and has the abdomen entirely ferruginousbrown.

Mub. Santa Posa, Mendoza (A. C. Jensen-Manrup)).
This species som what resembles Ornepes albonotata, André, in the form of the pronntum, lut otherwise is nearer to Psudelaploroptra flaromaculata, André, except in the longer and narrower pygidium. It may prove to be the female of $P$. rollei, 'Turn.

## Elaphroptera promissa, sp. n.

o. Head subrectangular, strongly rounded at the posterior angles, more than twice as broad as the pronotum, nearly half as broad again as long, thick and scarcely concave above; the eyes small and broadly ovate; the front divided by a longitudinal sulcus. Pronotum small, broader than long, scutellum small and narrow, rounded posteriorly ; the median
segment as long as the pronotum, very narrow at the base, broadened and obliquely truncate posteriorly, with a small tubercle in the middle just before the base of the truncation. Head shining, very sparsely and finely punctured, the thorax opaque and more closely punctured, the pronotum not excavated. Abdomen broad, sparsely and shallowly punctured; the basal segment with a shallow transverse groove before the apex and without hairs at the base; the second segment transversely and coarsely rugose, with a deep transverse groove at the apex bordered by raised transverse carinæ. Pygidium longer than broad, finely longitudinally striated, the apex smooth and broadly rounded, the epipygium broad at the base and produced laterally into prominent angles, thence narrowed sharply. Fifth ventral segment punctured, with obscure longitudinal striæ near the apex; the first ventral segment carinate from the base, with a triangular truncation at the apex, the groove between the first and second ventral segments deeply marked.

Ferruginous brown; the thorax and median segment fuscous; the front of the head and the anterior tibix above ochraceous.

Length 9 mm .
Hah. Chile.
Type in B.M.
'This is a true Elaphroptera, but differs in the much longer median segment and the absence of hair at the base of the abdomen from most of the known females. It will probably prove to be the female of $E$. hyalinipennis, Spin., but it would be unjustifiable to place it with that species until absolute certainty is attained.

## Ariphron excisus, sp. n.

i. Head large and moderately flattened, subrectangular, but strongly rounded at the posterior angles, broader than long, sparsely punctured, the vertex shining, the front subopaque and ininutely punctured between the coarser punctures. The front prominent between the antemæ and bilobed, the antennæ inserted near to each other in a space strongly depressed below the front, the clypeus also depressed. Eyes very small, almost round, situated near the base of the mandibles, which are large and prominent. Pronotum coarsely punctured, much narrower than the head, the median portion longitudinally elevated and $\Lambda$-shaped, pointed on the anterior margin, with a large, deep, smooth excavation on each side. Scutellum very narrow; the mesopleuræ
fincly and closely punctured, very prominent anteriorly, and almost toothed at the lower angle; a very deep groove between the pro- and mesopleura for the reception of the anterior femora. The anterior tibie are produced beneath into a compressed carina which is very deeply and narrowly incised before the middle. Merlian segment shorter than the pronotum, broadened and obliqucly truncate posteriorly, closely punctured, the sides of the segment delicately aciculated. Abdomen broader than the thoras, closely punctured, with rather long greyish pubescence on the sides; the first segment narowed and truncate at the base; the second punctured ruse, with a low transverse carina near the base and the apical marein slighty raised ; the pygidium narrow and convex, with a low, median, longitulinal carina, a small elongate-ovate truncation at the apex, the carina continued on the surface of the truncation almost to the apea. All tho ventral segments are rather closely punctured.

Fuscons, the legs fusco-forrugimons, the front of the head fulvous. The tarsal ungues are bluntly toothed near the base.

Length 9 mm .
Hab. S. Australia (?).
Type in B. M., purchased in 1567, apparently from Bakewell's collection.

I place this peculiar species in Aribhron with doubt. The sculpture of the ablomen is more like Tachynomyia, but in the excavated promotum, the prominent mesopleure, and the shape of the head it is much nearer Aripheron. The remarkable form of the anterior tibixe seems to be peculiar to the species, but they are not mormally formed in A. bicolor or A. tryphonoides. In tryphonoides there is a prominent projection on the anterior tibie above near the base.

## Tachynomyia adusta, Sm.

Thynnus adustus, Sm. Cat. Hym. B.M. sii. p. 43. n. 122 (1859), ㅇ.
Ěiurus pilosulus, Sm. Cat. Hym. B. MI. vii. p. ธ̄6. n. 10 (1859), ơ.
Several pairs taken in copula by Mr. G. A. Waterhouse at Killara near Sydney early in October.

## Tachynomyia vulpina, Sm.

EElurus culpinus, Sm. Cat. Hỵm. B.M. rii. p. 54. n. 7 (1859), ठ*.
In my revisinn of the group (P1oc. Linn. Snc. N. S.W. xxxii. p. 286, 1907) I gave this as a synonym of T. marens, Westw. A further cxamination has convinced me that the
species are quite distinct, the hygopyginm of $T$. vilpina being broadly subtruncate at the apex, in aldition to the difference in colour of the legs and wings; the abdomen is rather more shallowly punctured. The female described by me is that of true merens.

## Tachynomyia megacephala, sp. n.

or. Clypens finely and closely punctured, the apical morgin broadly smooth, a carina from the base not reaching the apex, narrowly produced and truncate at the apes. Head very large, broad and massive, deeply concave beneath, with a fringe of long, curved, pale fulvous hairs on the sides; the prominence between the antenne broadly truncate at the apex, not bilobed; the antema inserted farther from each other than from the eyes, the scapo scarcely longer than the two basal joints of the flagellum combined. The head is shining, deeply, but not very closely, punctured ; the posterior ocelli three times as far from the posterior margin of the head as from each other and more than half as far again from the eyes as from each other. Thorax closely and rather finely punctured, much more sparsely and coarsely on the dise of the mesonotren and scutellum; the pronotum narrower than the heal, the anterior margin slightly raised and thickened, the scutellum strongly convex and raised above the mesonotum, rather short and broadly truncate at the apex; the mesonotum is broad, measuring nearly 3 mm . between the tegulæ. Median segment and pleure opaque, finely and very closely punctured, the median segment rounded, with an almost obsolete sulcus from the base. Abdomen smooth and shining, fusiform; the basal segment half as broad at the apex as long, very narrow at the base, the second segment twice as broad at the apex as the first, slightly depressed at the base, the two apical segments sparsely punctured. Hypopygium short, projecting very little beyond the epipygium, triangular, produced at the apex into a short, blunt spine, the basal angles with a small acute spine.

Black; the apex of the clypeus, a narrow line on the apex of the interantennal prominence, the anterior margin of the pronotum narrowly interrupted in the middle, the tegulæ and the postscutellum pale yellow. Wings fusco-hyaline, darkest tuwards the apex, the posterior wings subhyaline; nervures black. 'The pleuræ and median segment thimly clothed with rather long white pubescence. The tibie without spines on the outer margin.

Length 14 mm .
Ann. \& Mag. N. Hist. Ser. 8. Vol.iii.

Hav. Cape York, Q. (Turner) ; April.
Type in B.M.
Very near T. flaropicta, Ritsema, the type of which came from Aru, but this is a more stoutly built insect and the wings are much darker, the head also is larger and more massive.

## Thynnus trisulcatus, Sm.

This female, of which the male is unkuown, is cortainly distinct from T. depressus, Westw., under which name I placed it with doubt in my recent revision of the family.

Thynnus (Zeleboria) monticolus, sp. n.
ठ. Clypeus produced and rather narrowly truncate at the apex, very finely and closely punctured, not carinated. Antenne inserted nearer to each other than to the cyes, as long as the head, thoras, and median segment combined, the apical joints rather feebly arcuate. Front very fincly rugulose, with a delicate longitudinal sulcus reaching the anterior ocellus. Head transverse, finely and closely punctured. Thorax finely punctured, the mesonotum with two longitudinal impresser lines on each side. Median segment lunger than broad, delicately aciculate, "ith sparse cinereons pubescence on the sides. Abrlomen suipectiolate, fusiform, longer than the head, thoras, and median serment combined, smooth and shining, with sparse and fine punctures. Hypopygium longer than broad, slightly narrowel to the apex, the apical margin truncate with a very short apical spine.

Black; the mandibles at the base, the anterior margin of the pronotum very narrowly and interrupted in the middle, and the middle of the postscutellum very pale yellow. Wings hyaline, nervures black. The second recurrent nervure is received at one-quarter from the base of the third cubital cell.

Length 14 mm ., exp. 27 mm .
Mab. The Australian Alps, Victoria.
Nearest to T. (Zeleboria) nitidulus, Turn., from which it differs in the frontal sulcus and in the colour, especially of the legs, which are black instead of ferruginous as in the allied species.

## Thynnus (Zeleboria) lavifrons, Sm.

Thynnus (Agriomyia) leorifrons, Turn. Proc. Limn. Soc. N.S.W. Ixsiii. p. 166 (1908).

I placed this female in the subgenus Agriomyia in my revision of the family, but it is almost certainly a Zeleboria, probably the opposite sex of $Z$. sexmaculatus, $S$.

Thynnus (Eolothynnus) halophilus, sp. n.
ठ๋. Clypeus convex, large and long, truncate at the apex, the middle sparsely punctured, the sides almost smooth, the labrum exposed. Front long and narrow, rather strongly punctured, the inner margins of the eyes almost parallel, the eyes long and narrow ; the antenur inserted much farther from each other than from the eyes and alnost as far from the apex of the clypeus as from the anterior ocellus, the prominence between them not much raised, bilobed and deeply emarginate at the apex. Thorax closely and rather finely punctured, the pronotum as broad as the head, broadly emarginate anteriorly, the anterior margin raised. Mesopleuræ rather coarsely punctured; the mesonotum marked with two shallow longitudinal sulci on each side; the scutellum rather large, truncate at the apex. Nedian segment sparsely, but very deeply and coarsely, punctured at the base, subtruncate and rugulose posteriorly. Abdomen elongate, about as long as the head, thorax, and median segment combined, the segments constricted molerately at the base and with a raised transverse mark emarginate in the middle just before the depressed apical margin, all the segments sparsely and finely punctured. Hypopygium rather broad, tridentate at the apex, the central spine long and slender from the base, more than twice as long as the two lateral ones. The sixth ventral segment has a very short and blunt spine at each of the apical angles.

Black; the mandibles (except at the apex), the sides of the clypeus, the inner margin of the cyes broadly as high as the base of the antennæ, the margins of the pronotum, broadly interruped in the middle of the anterior margin, the tegulx and a curved line above them, a square spot on the posterior margin of the mesonotum, a vertical band emarginate posteriorly on the mesopleuree below the anterion wings, a spot before the base of the intermediate cosæ, a transverse mark near the apex of the scutellum and a spot on each side at its anterior angles, the postscutellum, an oblique band on each side on the apical portion of the median segment, curved at the apex and continued on the sides of the segment, and a short transverse band on each side of abdominal segments 1-5 pale yellow; the legs pale ferruginous. Wings hyaline, nervures pale testaceous, the stigma light ferruginous.
Length 6 mm .
Hab. Cape York, Q. (Turner); April and May. Type in B.M.

Tery near cerceroiles, Sm., Zut the heal and clypens ane much longer and narrower than in the typical form of that insect and the thorax is much inore fincly punctured. It is a much smaller and less robust species, and the colour of the legs is different.

In my key to the females of Thynnus I have placed those of the subgenus Aiolothynus amome those with the tarsal ungues simple; but in all except those of the westwoodii group there is really a minute tooth near the midulle. In all the ungues are very feeble and small.

## Tliynnus gravidus, Westw.

In my revisim of the Thymide I suggester that this might lie the fomate of Oncomhinus comethositus, but on a further examination of the type at Oxiond I feel little doubt that Westwood was correct in commecting it with his T. Filugii, and that the female which I describel as that of T. lilugii, Westw, should belong to the chosly allied species $T$. poultomi, Tum., which was comfused both in the Oxford and British Musenms with T'. Vilugii. The two females agree in the structure of the hind fomona, the strongly developed spur of the anterior tither, the shape of the rygidium, the sculpture of the first two dorsal segments of the ahlomen, and the bituberculate prominence between the antemas. The pronotum in T. poultoni is, however, not concave on the sides, and I lave been umalile to examine the mouth-parts; the fifth ventral segment in T. gracidus is longitudinally striated at the apex, whereas in $\dot{T}$. poultoni it is transversely striated. The difference in colour is striking, considering the close resemblance between the males.

## Thynnus bidens, Sauss.

In my recent revision of the Thymide (Proc. Linn. Soc. N.S.W. xexiii. p. 249, 1008) I gave this as a synonym of I. gracilis, Westw., but the hypopygium is quite different, being shorter, withont basal spines and with the sides bent upwards. Thymmus ciduus, Sauss.. is the female of this species, but is very near $T$. gracilis, $f$; the head being rather longer in T. gracilis.

## Thynnus pseudomelleus, sp. n.

o. Clypens truncate at the apex, the angles very slightly prominent, shallowly and rather closely punctured, very narrowly truncate at the base and comected by a broad
carina with the prominence between the antenne; the labrum scarcely visible. The antemæ inserted a little farther from each other than from the eyes, the prominence between them broadly $V$-shaped ant divided by a longitudinal sulcus. Head clusely and rather shallowly punctured, coyered with rather long greyish pubescence. Thorax closely punctured, the pronetam narrowed anterionly, the anterine margin very slighty raised, straight and narrower than the head. The disc of the mesnotum is bordered on the sides by a raised curved carina above the tesula, and the longitudinal sulci usually present in the family are absent. The scutellum is large, broadly rounded at the apex. Median segment obliguely truncate from a little behind the pritscutellum, rounded at the sides, closely and shallowly punctured and with rather long grey pubescence. Abdomen elongate, the segments slightly depressed at the hase, shiming and rather sparsely punctured ; the transverse grove between the first and second ventral segments is shallow. Epipy inum very coarsely punctured, without a produced dorsal plate, semicircularly depressed at the apex. Hypoprgiam shont, produced into a stout spine projecting a little keyond the epipygium.

Black; the mandibles (except at the apex), the clypeus, the prominence between the antema, the margins if the cyes interrupted at the summit, continued in a narow band on the posterior margin of the head bisinuate in the midille, the pronotum (except a small black spot on the middie of the anterior magin and a large trameverse mark on mach side), the mesopleure in front, a curved mark on the mesnnotum above the tegule, two obligne marks uniting posterimity on the dise of the mes motum, the scutellum with the hase rather broadly black and a narrow transverse black mak wn each side near the apex, the postscutellum, a large mark trilobed posteriorly at the apes of the median segment and produced laterally on to the sides of the segment, the cosin and femora beneath, the tegulse, and a broad band near the apex of each abtuminal segment except the seventh pate yellow ; the bands are continued beneath on ventral sionments $2-5$. Femora and tarsi dull ferruginous, the femora very pale jellow above. W'ings hyaline, tinged with yellnw at the base, nervures and stigma ferrginous.

Length 19 mm .
Hat. Glen Innes, N.S.W. (Froggatt).
'I'ype in coll. Froggatt.
Near T. frenchi, Turn., but the scutellum is shorter and differently shaped in addition to the considerable differences
in colomr; the clppens is also rather shorter and not pointerd at the base as in T'. frencli. 'The markings are very similar to those of T. melleus, Westw., but the colour is pale yellow instead of orange.

Thynnus atrocior, sp. n.
己. (lypeus coarsely punctured, some of the punctures confluent longitudinally, very prominent at the extreme base, then ilepressed and flattened to the apes, where it is broadly frumeate, with very slightly prominent angles; the labrum projectitg a little beyond the clypern, mot bilobed. Naxilla with a fringe of very long hairs on the outer margin. Head closidy and rather deeply punctured, the antemo of equal thickness thronghout, a litule further from each other at the base than from the eyes, the second juint of the flagellum roly fwo-thirts of the length of the thit ; the prominence between the antemme broadly rommled at the apex and connected by a very shont carina with the printed base of the clypeus; a delicate carina from just below the anterior rectlus reaching the apex of the interantennal prominence. Thomas closely punctured, the pronotum with a transverse groove just helind the anterior margin, the anterior angles searecty prominent; the mesonotum with the nsual two longitudinal sulci on each side, the imner one much the decpest ; the scutcllum about two-thirds of the length of the mesmotum, convex and lomgitulinally subearinate in the middle. Median segment mather finely rugose, with a longithanal depression from the hase, ubligue and shining jinsterionly, with a duep sulcus on each side close to the apex. Abdomen chsely, but not deeply punctured; the first segment as hocad at the apex as the second, the segment feebly constricted at the base, and narrowly dep ressed on the apical margin, the first ventral segment divided trom the second by a moderately deep growe, the sixth segment with a short spine on each side at the apical angle; the dorsal plate of the epipygium flatly producel, truncate at the apex and coarsely longitudinally striated. Hypopygium prominently rounded at the lasal angles, but not toothel, thence rather broadly produced and rounded at the apex, without an apical spine; transversely striated above near the base, "ith a longitudinal, low carina near the apes; punctured beneath, with a longitudinal carina.

Black; with close grey pubescence, longest on the sides of the lead and abdomen and on the pleuræ, the spines of the tibiæe whitish, the mardibles dark fusco-ferruginous.

The fattened portion of the clypeus and the extreme apex of the median segment are without pubescence and shining, the remainder of the insect opaque. The anterior cosxa are very slightly concave beneath. Wings hyaline, nervures black.

## Length 18 mm .

Mab. Gippsland, Victoria.
Very near T. atrox, Turn., from Western Australia, but the sculpture of the clypeus is different, and the spines at the basal angles of the hypopygium are not developed. The tubercle at the base of the second ventral segment, which is strongly developed in $T$. atrox, is absent in the present species.

## Thynnus multistrigatus, sp. n.

7. Head shining, very sparsely, but rather deeply punctured, more closely on the front between the antennæ, very slightly convex, more than half as broad again as long, and rounded at the posterior angles; the eyes oval, not tcuching the base of the mandibles. Thorax and median segment shining and very sparsely punctured; the pronotum as broad as the head, nearly twice as broad anteriorly as long, very siightly narrowed posterionly, with a row of sctigrous punctures on the anterior margin which is almost straight. 'The scutellum is narowed and broadly rounded prsteriorly; the median segment very short, obliquely truncated from just behind the scutellum; the pleure smooth and shining. Abdomen slining, segments $3-5$ almost smooth; the first segment truncate anteriorly, the face of the truncaticn strongly concave, the dorsal surface rugosely punctured at the base, with a patch of long pubescence in the middle, and with three transverse carine near the apex, which are separated from the recurved apical margin by a rather broad transverse groove. Second segment with about twenty transverse carinæ, those near the base low and fine, very near together, those near the apex much stronger and farther apart. Pygidium truncate posteriorly, strongly constricted before the base of the truncation and transversely striated, the surface of the truncation ovate and smooth, the hypopygium not emarginate at the apex. Fifth ventral segment coarsely longitudinally striated and deeply emarginate at the apex. The basal joint of the intermediate tarsi is broad and Hat, but not as strongly so as in some of the allied species. The clypeus is transverse, convex in the middle but not carinate, and closely punctured.

Black; the scutellum, a spot on each side of the first and
second abdominal segments, a band near the apex of the third and fourth, almost interrupted in the middle on the third and broadly intermpted on the fourth, the apex of the first ventral segment and a large sput on each side of segments $2-4$ yellow; antemat piccous; legs fusco-ferruginous beneath.

## Length 18 mm .

Hab. Richmond, N.S.W. (Froggatt).
Type in coll. Froggatt.
This is the female of a suecies helonging to the section Zaspilothymnus, Ashm., but the licad is not iemply groovel as in leachitlus, Westw., which Ashmead takes for the type of his gems. But other species in which the male does not seem to differ in structure from leachiellus (notably T. veinatis, 'I'urn.) have the head of the iemale without groners, so that I cannot regard this character as of more than specific importance.

In my key to the species of Thynnus (Proc. Limn. Sioce. N.S.W. xxxiii. p. 84, 1908) I have placel T. sedurtor, Sim., among the species without a spine at the apical angles of the sixth ventral segment. This is an error, for the spine although short and blunt is distinctly visible. On the other hand, T. anchorites, 'Tum, has heen phaced, by an oversight on my part, among the species in which the spine is present, whereas there is no trace of a spine.

## Thynnus salulosus, 'T'urn.

Thymnus sabuluzus, Turn. Proc. Limn. Soc. N.S.W. xxxiii. p. 20 (1908), 우.

This will probably prove to be the female of T. annatus, Guér. (nigropectus, Sm.), which is a wilu-rancing species, the localities for specimens in the British Muscum being Siwan River, Rueburne, N.W.A., and Alexandria, near the eastern breder of the Northern 'Territory. 'Thongh the head of $T$. sabulosus is not deeply grooved as in most species allied to $T$. clentatus, Fab., it certainly belongs to that group.

## Thynnus picticollis, Turn.

Thymmes picticollis, Turn. Proc. Linn. Soc. N.S.TV. xxxiii. p. 216 (1908), 우.

This belongs to the group Zaspilothynnus, Ashm., and may prove to be the female of $T$ : ochroceplatus, Sim. The first joint of the intermediate tarsi is very strongly flattened and broadened, and the intermediate tibiae are also broader
and stouter than in mosi of the allied species. The pygidium is not emarginate at the apex as it is in typical Thynnus, agreeing in this point with other species of the Zaspilothynnus group, which, when the family is more studied, may be raised to generic rank, as is done by Ashmead.

## Thynnus brisbanensis, sp. n.

ठ. (Clypeus broadly truncate at the apex, the angles slightly prominent, pointed at the base and connected with the interantemal prominence by a short and narrow carina, sparsely punctured and very finely longitudinally striated; the labrum prominent. Antemme insertel a little further from each other than from the eyes; the prominence between them broadly triangular, with a carina from the apex extending to the anterior ocellus. Frout closely and finely punctured-striate, the vertex closely punctured. Pronotum broader than the head, closely punctured, with a very shallow transverse groove behind the feebly raised anterior margin. Mesonotum very closely punctured between the two longitudinal lateral sulci, the centre more sparsely punctured; scutellum large, very broadly rounded at the apes, and sparsely punctured ; tlie postscutellum almost thansverse, reaching but not projecting beyond the truncation of the median segment, which is broad and slightly oblique, not quite vertical, the surface very finely rugulose. Abdomen subconical, the iirst segment truncate anterionly, slightly rounded at the anterior angles, as broad at the apex as the second segment, the whole abdomen shining and rather sparsely punctured, the segments not constricted. The dorsal plate of the epipygium is produced, longitudinally striated, and shallowly emarginate at the apex. Sixth ventral segment with a short spine on each side at the apical angles. Hypopygium with five spines, those at the basal angles blunt and not very prominent. The first ventral segment is longitudinally carinate and obliquely truncate at the apex, the groove separating it from the second segment is shallow.

Black; the mandibles (except at the apex), the clypens, the labrum, a broadly V-shaped mark between the antenne, the margins of the eyes narrowly interrupted at the summit, the anterior and posterior margins of the pronotum, a spot on the mesopleuræ below the anterior wings and another above the base of the intermediate coxæ, the tegule and a narrow oblique line behind them, a broad median mark on the posterior margin of the mesonotum, the apical half of the scutellum and a spot on each side at the anterior angles, the postscutellum, the median segment on the middle and the
sides, the coxæ beneath, the projection of the mesosternum between the intermediate cose, the truncation of the first abdominal segment with a longitu linal black mark in the middle and a small black spot on each near the base of the truncation, a broad band emarginate in the middle and less deeply on the sides posterinily above the truncation and not separated from it, a broad band rather narrowly interrupted in the middle and emarginate on each side posterionly on dorsal segments $2-6$, the apex of the first ventral segment and a large spot marked with a narrow l, lack lunule on each side of the ventral segments $2-5$, largest on the second and gradually diminishing in size to the fifth, yellow. Wings hyaline, nervures black.

Length 21 mm .
Mub. Strarbroke Island (A. J. Turner) ; January.
'I'ype in coll. Froggatt.
Allied to typical Thynnus by the hypopygium, but in some prints nearer to $A$-hmead.s gronp Zuspilothennus. It is very nearly allied to I'. elgnori, Turn., from Cape York, but in that species the hypopyemon is narrower at the apex and the logs are ferruginous; it is also very much smaller than the present species. Until the female is know: I think it befter to connect these two species with the typical Thynmus group rather than with Zuspilothynnes, though it is guite [1"ssil,le that the females, when discovered, will prove to be nearer the latter.

Thynnus ventralis, Sm., var. desiccatus, var. n.
Specimens of this species received lately by the British Museum, collected by Mr. H. J. Hillier at Llermansburg, Central Australia. differ from the common form from the N.W. Coast as follows :-
6. The yellow sputs on eacis side of the f suth and fifth dorsal abdominal segments, which are always present in the specimens I have seen of veutrulis, are absent in var. desircutus, in which also the femora and tibix are ferruginous instead of yellow, and the mesopleure, mesonotum, metasternum, and intermediate and posterior truchanters and coxre black instead of yellow.
of. The variety has the clypeus black instead of yellow and the anterior margin of the pronotum is distinctly raised, which is not the case in the type of the female, the sternum and coxa are also black in the variety, except a small yellow spot at the base of the intermediate and posterior coxa. There are four males and two females in the Museum collection.

## XVIII. - The Type of Exocœtus exiliens (L. Gmel.). By Albert Günther, F.R.S. \&c.

In the collection of Linnean specimens of Fishes, now in the possession of the Linnean Society of London, there is a specimen of Exoctetus, sent by Garden to Linnæus from Carolina at an uncertain date. I have already mentioned it in my list of Limean specimens in Proc. Limn. Soc. 1899, P. 37, no. 165 ; but I then failed to recognize its importance; it undoubtedly proves to be the type of (L.) Ginelin's Exocoetus exiliens.

It is the dried skin of a fish 6 in . long, which had been preserved in the manner of a botanical specimen; the head has been compressed and crushed; both sides of the skin are preserved, and the vertebral column shows through large vacuities in the skin; the fins are collapied, with the exception of the pectorals, which are stretched to their full width and glued to a supporting piece of paper. The specimen is labelled by Garden, No. 25, and in Linnés handwriting Exoccetus volans.

It is not necessary to repeat here Gmelin's diagnosis of the fish; and I may at once proceed to supplement it as far as the dilapidated condition of the specimen will allow.

The length of the head is contained $4_{8}^{5}$ times in the total (without caudal); the snout seems to have been rather pointed. The pectoral fin extends nearly to the candal, and consists of 14 rays on one side, and 15 on the other; of these the first is simple ( 33 mm . long), half as long as the second which is branched; however, on one side, a rudimentary ray ( 3 or 4 mm . long) can be made out to precede the first ray *; none of the rays are lamellated in the basal portion as in E. lamellifer: The ventrals are inserted midway between the gill-opening and the root of the caudal, and reach nearly to the base of this fin. The dorsal and anal fins are collapsed, firmly adhering to the skin of the tail, so that it is difficult to

[^18]come the rays, but the former seems to be formed of 12 or 13, and the latter of 9 or 10 rays. The dorsal fin commences fur in adrance of the anct, in fact, the first anal ray is opposite 10 the sixth of the dorsal ; on the other hand, the basis of the anal extends rather more backwarls than that of the dorsal. The dorsal is elevated thronghout its length, some of the hinder rays reaching nearly to the caulal. The lower candal love in its present dried condition is consideralaly longer than the hear ( $(33 \mathrm{~m}$ m. m ). The majonity of the scales are lust, hut there seem to have been 42 in a lomemdinal series on the side of the horle, and $25^{\circ}$ betwonn head and dorsal fin; I count 9 longitudinal series above the first anal ray.

The hinder pant of the domsal, prisoibly the entire fin, was h, lack; the anal whitish, the estremity of the candal hackish. Basis of the pectomal hackinh, then follows a hroad white eross-land from the lower to the upper margin; the posterion half of the fin black, with traces of a narrow white margin. Anterior half of ventrals whitisli, posterior blackish. No black band across the abdomen.

The characters given above tally very well with the notes left by Gmelin, except the numbers of the fin-rays, which Gmelin states to b: 11.10, A.11. However, no grat weight can be attached to this discrepancy, consilering the frequent inaccuracies which we meet in this respect in (amelin's edition, as well as the great difficulty in ascertaining the correct numbers in this particular specimen, the fins of which must have been always (since it came into Limeés possession) in the same collapised and dried-up condition. Mr. Tate Regan assisted me in lixing the numbers by counting the swelled joints at the base of the fin-rays.

Gmelin says: "pectorales radio primo et secundo brevibus"; we must therefore conclude that he saw and counted the rudimentary ray which I find on one side of the specimen, but not on the other. But this condition is very different from that obtaining in the young indivi luats which Lütken (Vid. Meddel. $1876,1 \mathrm{p}, 110$ et seq.) determined as E. c.riliens, and which have that anterior ray much more developed, nearly one half the length of the second.

Jordan and Evermann (Fish. N. Amer. p. 732) a-cribe the priority of the original description and the name "exsiliens" to P. L. S. Müller, giving 176 as the date. This is an error. 'That date is the year of publication of the first volume of Müller's work: the description of our fi-h appears in the seventh volume (Siuplement) dated 1889, a year later than Gmelin's edition of the 'Systrma mature,' and published several yeats after Miiilen's death. Besider, Miiller (or, after
his death, his Editor) had no specimen, and merely reprotuced in a German translation the original Latin description in Gmelin's edition; this description is acknowledged by him as being taken from "Linnæus" (p. 210).

Gmelin's E. exiliens is at present known from the Tropical Atlantic only; in fact, from the type alone. I am unable to identify it with any of the species, as distinguished by Valenciennes, Brown Goode, Jordan and his fellow-labourers. The question whether a high dorsal fin with convex upper margin (as observed in our specimen) is invariably, or only in a part of the species of Errocutus, a sign of youth, has not yet been satisfactorily settled. But there remains the backward position of the anal fin: a character which precludes the idea of associating our specimen with E. rondeletii, lamellifer, or the E. exsiliens of Jordan and Evermann. In this respect it comes nearest to E. kutoptron (Bleek. *), E. robustus (Gthr.), and E. attipimis (C.V.). In fact, I should be inclined to regard the last, which was obtained in the Indian Ocean and near the Cape of Good Hope, as a synonym of E. exiliens (L. Cm.), if Valenciennes did not ascribe to it twelve rays in the anal fin. On the other hand, the figure which he gives of this fish shows eight or nine only $\dagger$. Finally, the fish from Wood's Hole, which Jordan and Evermann continue to figure as late as 1905 ('Hawaii Shore-Fishes,' p. 133, fig. 45) as Ewocuetus volitans, may well prove to be a more advanced stage of growth of Exoccetus exiliens (L. Gm.).

## XIX.-Some Mummuls from N.E. Kimberley, Northern Australia. By Oldfield 'Thomas.

The British Museum has acquired from Mr. J. P. Rogers a few mammals collected by him on Parry's Creek, near Wyudham, N.E. Kimberley, and these prove to be of such interest as to deserve a short account. Of the six species represented three need new names.

It is interesting to notice that there seems to be a greater

[^19]difference between the mammals of this district and those of the comparatively arljacent Arnhem Land, Port Essington, \&ec., than between the latter and Eastern Australia, more than a thousand miles distant. For example, typical Dasyurus hallucatus ranges from Inkerman, E. Queensland, to Port Essington, but is replaced in Kimberley by subip. exilis. Again, Chalinolobus nigrogriseus occurs at Port Essington and at Moreton Bay, New South Wales, while we here have the new form Ch. rogersi. The north and south political line dividing South Australia and its Northern 'Territory from Western Australia would therefore seem also to form the boundary-line between the two faunas.

## 1. Chalinolobus rogersi, sp. n.

ơ. No. 9. Parry's Creck. Alt. 10'. 4th September, 1908. Type.

A small species, black, with hoary tips to the hairs.
Most nearly allied to Ch. nigrogriseus, Crould, with which it shares the more normal shape of the skull as compared with the peculiarly shaped skall of Ch. gouldi and morio. Ears and tragus about as in Ch. nigrogriseus. Fur soft and fine; hairs of back about $4 \frac{1}{2} \mathrm{~mm}$. in length. General colour grey (grey no. 6), resulting from the hairs heeine deep brownish black, wit! their tips ( 0.5 mm .) dull whitish, the whole giving a rather striking and musual hoary appearance to the bat. Colour below similar, but the light tips are broader and more drab in tone, at least on the body. On the wing-membrane, however, which is thickly hairy outwards to a line joining the elbow and knee, the hairs are prominently whitish for their terminal halves, as are those edging the interfemoral membrane. Wing-membranes brown, a narrow whitish line edging the plagiopatagium. A well-marked postcalcareal lobe present. Tip of tail little projecting.

Skull smaller than in Ch. nigrogriseus and its brain-case rather more inflated. Other characters and relative size of teeth as in that species.

Dimensions of the type (the starred measurements taken in the flesh) :-

Forearm 34.5 mm .
Head and body $45^{*}$ : tail $34^{*}$; ear $6^{*}$. Third finger, metacarpal 32, first phalans 16 ; luwer leg and hind fuot (c. 1.) 21.5 .
skull : condylo-basal length 12.2 ; basi-sinual length $9 \cdot 9$;
zygomatic breadth $8 \cdot 6$; mastoid breadth $7 \cdot 4$; palato-sinual length $4 \cdot 6$; front of canine to back of $m^{3} 4 \cdot 5$.

Type as above.
This well-marked little species, which I have named after its discoverer, may be readily distinguished from its only near ally Ch. nigrogriseus by its hoary colour and the smaller sizs of its skull.

## 2. Mus ferculinus, Thos.

o. 2. Parry's Creek.

I fail to find any satisfactory means of distinction betweon this and the type from Barrow Island, N.W. Australia.

## 3. Mesembriomys * argurus indutus, subsp. n.

б. $1,6,8 ;$ \&. 4. Parry's Creek; near sea-level.
similar to typical argurus in all respecte, except that the tail, instead of being wholly white above and below, is distinctly and sharply bicolor, dark brown along the upper surface, white on the sides and below; it is also rather mure heavily pencilled.

Dimensions of the type (measured in flesh) :-
Head and body 107 mm . ; tail 96 (not quite perfect, another specimen 109) ; hind foot 22 ; ear 18.

Skull : greatest length 33.5 ; basilar length 25.7 ; nasals 11.6 ; interorbital breadth 4.8 ; palatilar length 15 ; diasiema $8 \cdot 6$; palatal foramina $6 \cdot 6$; upper molar series 5.5 .

Type. Adult male. Original number 1. Collected 13 th Aug., 1908.
'These specimens are the first we have harl in skin of this form of Mesembiomys, the type and only known example of M. argurus heing in spirit. That type was purchased from a collector who traversed Australia from north to south, and it is probable that it was obtained in the interior desert-region, which would account for its whitened tail as compared with the brown tail of this northern coast subspecies.

Mr. Rogers states that this animal has a thickened fatty tail, as also has M. pedunculatus, this character being rarely found among. Muridie, although in other groups it often occurs in the inhabitants of desert regions.

[^20]
## 4．Petrogale inornata，Gould．

## む．5．Parry＇s Creek．

This rare species has not hitherto been represented in the Muspum Cullection，as the type，describel hy Gould in 1842， was reclaimed hy the collector，Mr．Bynoe，and has now disappeared．

## 5．1soodon macrurus，Gould．

む．7．Parry＇s Creck．
6．Dasyurus hallucatus exilis，subsp．n．
ふ．10，11．Parry＇s Creek．
A smaller paler formi of $D$ ．hallucatus．
size decidenly less than in the hallucatus．General colour above paler，owine to the gromm－colour itself buing paker（apmondhine＂Mab－grey＂），while the white spots are not mily very mumerous，hut are not so sharply defined， white hairs strageling over from them to the darker gromul－ colour．Ears，siles of neck，under surlace，and uppror sides of hamls and feet witite or whitish，insteal of pale drables． ＇I＇ail thimer and less heavily pensilled than in holluculus，its urn wide lishty gizzled drably fin thee－fourths its length， the underside and tip dark brown $\%$ ．

Skull as in tha：hallucatus，but rather smaller throughout． ＇Teeth distinctly smaller．

Dimensions of the type（measured in flesh）：－
Head and boly 266 mm ．；tail 219 ；himd foot 4.3 ；car 3．5．
Skull：basal length 5s；greatest breadth 39；interorbital heradth 14 ；palatal length 32.5 ；combined length of three anterior molariform teeth $11 \cdot 6$ ．

Type．Old male．Original number 10．Collected Sth Sep－ tember， 1908.

A very well－marked form which many naturalists would ennsider deserved specitic rather than subspecifie distinction． ＇the balance of convenience，however，appears to me to be on the side of recognizing in its name that it is related to and locally representative of the species of which I call it a subspecies．A simple binomial gives no che to its relationship．

[^21]XX. - Votes from the Gatty Marine Laboratory, St. Andrews. —No. XXXI. By Prof. M‘Tvtosh, M.D., LL.D., F.R.S., \&c.

## [Plates V. \& VI.]

1. On a Young Stage of Gadus luscus with bold transverse bars of pigment.
2. On the British Spimide.
3. On the Spionide dredged by M.M.S.' 'Porcupine' in 1869 and 1870.

## On a Young Stage of Gadus luscus with bold transverse bars of pigment.

The example (Plate V. fig. l), which measured 70 mm . in length, was thrown alive on the sand by a runlet of seawater near the Pole Rock, adjoining the West Sants, St. Andrews, on 3rd April, 190s, along with a young limg of $7 \frac{1}{2}$ inches in the holdly banded condition. The young bib hat a brownish-red colour with rery distinct black bars, a coloration which, like that of the young cod, may be protective amongit the seaweels and rocks. The dors?l surface of the head is covered with dark pigment, a pale band separating this from a dark band joining the upper border of each operculum. A broad dark belt passes downward below the interval between the 1 st and 2 nd dorsals to the ventral border; and the abdomen in front, almost to the opercular aperture, has a considerable amount of pigment. The most perfect band is a broal one which has its anterior border at the last third of the 2nd dorsal and passes with a slight slope backward to the base of the lst anal. Its posterior edge is a little behind a line joining the intervals between the 2nd and 3rd dorsals and the anals. The last area of dark pigment occupies the region exteuding behind the 3rd dorsal and the 2nd anal to the base of the caudal rays. The dorsal and ventral edges of the body have much black pigment; and an intervupted line of distinct and larger pigment-specks passes from a point a little behind the cye neally to the end of the 3rd dorsal, and at a short distance from the dorsal edge. A similar line is visible close to the base of the 2nd anal, and it may have extended further forward in life. Besides the bars the skin is covered by a general dusting of black specks, and these extend orer the chin, opereular region, the median fins, especially the lst anal and the anterior part of the ind. The dorsa's show fewer specks. At the base of the pect mat dorsaliy is a patch of black pigment, and at a somewhat higher level in

Ann. \& Mag. A'. Hist. Ser. 8. Vol. iii.
front of it is a black spot on the operculum. The number of fin-rays in the lst anal is 31, a larger number than has been met with in any example of the yomer of the poor-cod (Gadus minutus) over an area stretching from the North of Scotland to the Thames. The lst branchial arch bears 20 filaments and 15 gill-rakers, the former a comparatively high number, and, moreover, they are ranged along the entire length of the gill-arch, whereas in the examples from the Thames they diminish rather abruptly betore raching the ventral edge. The 2nd, Brl, and 4th arches respectively have 15, 13, and 11 gill-rakers. In the pomer poor-cod * of the same size from Aberdeen the numbers in each case were notably higher, though the long filaments at this stage had a similar shape.

## Young poor-cod same length as young bib.

Gill-ralkers.

| I. | II. | III. | IV. |
| :---: | :---: | :---: | :---: |
| 27 | 19 | 16 | 16 |
| 19 or 20 | - | 17 | - |
| 24 | 18 | 14 | 12 |

The long filaments in the poor-cod of the same length are, like the example of the bib, long and slender.

In comparing the specimen from St. Andrews with examples of Cindus luscus of the same lencth from the estuary of the Thames, a noteworthy feature is the greater depth of the body and the high arch formed by its dorsal edge in the southern forms. The length of the lst anal in the St. Abdrews example is shorter than the pre-anal outline, that is, the distance from the anus the tip of the snout; whereas in the southern the pre-anal ontline is shorter than the length of the base of the lst anal fin. Again, the proportions of the lst and 2nd anal fins in the respective examples differ, greater inequality being present in the southern forms. The two anal fins are more distinctly separated in the St. Andrews form, yet Schmidt $\dagger$ holds that in the bib they are practically connected and that the highest point of the 3rd dorsal and the 2ud anal lies far back, so that the anterior parts of these fins are almost parallel, a feature not evident in the St. Andrews example. The position of

* I am indebted for a series of these to the Fishery Board for Scotland.
+ Meddelser Fra Komm. for Harundes $\phi$ felser serie Fiskerei, Bd. ii. p. 57 \&c.
the anus in the latter is somewhat behind that usually seen in the adult. Further, each specimen from the Thames has a dark pigment-band, which is visible after ten years' prescrvation in spirit, on the free edge of the caudal rays, which also showed less of a median indentation than in the St. Andrews specimen. The barbel in the latter is also thicker and slightly shorter, whilst the eye is proportionally larger. Some of these differences may be due to the precocity of the southern examples of the same length; for in the essential structural features the specimen of 77 mm . from St. Andrews pertains to Gadus luscus and diverges from the poor-cod (Gadus mimutus). Whilst young forms of the latter are not uncommon in St. Andrews Bay, in consonance with the prevaleuce of the adults, the bib is less common, and fow or none of 70 mm . have been previously obtained. It appears to be otherwise in regard to the poorcod in Norwegian waters; for it is stated in the 'Scandinavian Fishes' that neither adults nor fry are ever seen close inshore, nor are they taken by the seine.

Allusion has often been made to a banded stage in the life-history of the bib. Thus Dr. Günther * mentions that the bib has cross-bands during life, and with a black avillary spot. Dr. Day $\dagger$ describes them as 5 or 6 broad vertical bands of rather darker colour descending from the back to the lower surface, meeting those of opposite sides. Mr. Couch $\ddagger$ and Malm $\S$ also allude to the same feature as an occasional occurrence. In the remarks on the bib and the poor-cod in 1888 || it was stated that the irideseence of the bib resembles that of the bronze-winged pigeon, the pale streaks on the sides occurring in broad blotches between the darker pigment-bands. Yet amongst many young bib captured along with young poor cod, soles, and other forms in the nets of the shrimp-trawlers of the Thames, no banded forms were met with, and some were of the same length as the specimen here dealt with, whilst others were shorter or longer. Similar bands to those described in the examples from St. Andrews ( 70 mm . in length) occur in another 75 i in. long. The first is a band in front of the first dorsal fin and including its anterior third and thence to the pectoral. The second is a broad bar of dark pigment, separated from the former by a pale belt, which extended to the anterior third of the secind dorsal. A broad pale band followed, and then a very well-

[^22]marked and broad belt from the posterior third of the second dorsal sloped downward and slightly backward to the ventral border. Traces of the dark band at the base of the tail are also visible, and the dark border to the tail is evident. In this example the filaments on the first gill-archand the gillrakers are exactly as in the young form as regards number, though the filaments presented a distal dilatation and terminated sooner ventrally than in the younger form of 70 mm .

## 2. On the British Spionide.

The Spionidse were included by Dr. Johnston in the Catalogue of the British Museum under the Ariciidse, a group which comprised representatives of various families. He recognized for the first time several, e. g. Nerine rulgaris (=scolecolepis rulyaris), besides Nerine ronioreplula ( = Netine foliosa, Sars), ǐpio filicornis, (). F. M.. Spio seticomis, O. Fabr., and Lencodore ciliutus, Johnst. In the 'Invertebrate Marine Fana of Plymouth' (1901) no spio is recorded, but Scolecolepis culyaris, Johnst., Nerine fuliosa, Sars, and Nerime cirrululus, Delle Chiaje, Aomides oryycophulu, Sars, Polydora ciliuta, Johnst., P. flava, Claparede, $P$. coecu, (Firsted, and $P$. hopluro, Claparède, are entered, besides Scolecolepis giurdii, De Quatrefares, a symonyin of Scolecolepis vulgaris.

In Merine foliosa, Sars, the head forms a somen hat blunt cone, the dorsal ridge terminating posteriorly in a rounded enlargement followed by a short tentacle. The palpi are clongate and tapering. The body is from 6 to 8 inches in length and nearly $3_{8}^{3}$ in. broad, somewhat flattened dorsally and slightly conves ventrally, little tapered in front, but gradually diminishing posteriorly to the crenate anus, and in one a cirrus in the median ventral line and longer than the diameter of the rent occurs. The segments are about 200 . In extrusion the proboscis forms a short crlinder, the free margin presenting an irregular series of frills, whilst ventrally the column is marked by longitudinal groores. Occasionally in full protrusion two prominent lobes occur distally with a small bilobed process above and a single lobe below, whilst within the frilled margin laterally and inferiorly is a crenate brown line indicating a differentiation.

In the anterior region of the body (in spirit, where both fillets are present in the feet and where the branchise are large, each segment dorsally shows two transverse ridees
and a median furrow; whereas ventrally the segment is undivided, each being separated by a deep furrow at the junction in front and behind. In the next region, where branchire are less, the dorsum has an elevated transver.e ridge with a narrow groove and a belt in front and behind, Ventrally a broad ridge with a furrow, and a narrower belt in front and behind, occurs. Still further backward, and where the branchia is represented by a rounded papilla, the dorsum shows an elevated transverse band with a more or less distinct median furrow, an enlargement in the centre of the dorsum anteriorly and one at each side, the intermediate region being marked by transverse lines. On the ventral surface a similar elerated transverse band is present, but the lateral enlargements are indistinet, and though there is an interrupted median band no median enlargement of the transverse band is visible.

The feet are furnished with branchix from the second backward, and they are amalgamated with the superior lamellæ from the 2nd to bevond the 50th. The interlamellar notch is distinct. The ventral lamella, at first prominent and rounded, becomes narrower and elongaied from above downward on the appearance of the winged hooks. The latter occur in the superior division about the 7()th bristled foot (Mesnil gives the 65th). The bristles iu the upper division in front form two groups, a long upper series and a shorter inferior, all curved, dappled, and finely tapered. At the foot just mentioned (70th) the branchia has lost much of its external frill, and is again separated inferiorly from the posterior fillet of the upper division of the foot, which rises into a prominent border superiorly. The anterior fillet has disappeared in both divisions, and the fillet from the second ring of the segment runs up behind the posterior fillet at its ventral edge. The bristles in the upper division remain simple, but are more slender than in front. The inferior division carries winged hooks, with the exception of a few bristles superiorly and inferiorly. The chief changes toward the posterior end are the diminution of the branchia (which at the 125 th foot forms a process less than the vertical diameter of the upper fillet), the diminution in the number of the superior bristles (which are in a single fascicle), the abbreviation of the upper border of the long fillet of the ventral division, and the increase and prominence of that part of the fillet bearing the bristles and hooks. Finally, the branchia diminishes to a minute rounded papilla, the upper fillet is short and almost semicircular, whilst a broad gap separates it from the inferior
fillet, which, though diminished, resembles that in front, viz., has a more prominent margin at the lower half.

It is strictly an inhabitant of the sand.
Part of Dr. Johnston's description of Neime coniocephala would apply to Nerine cirratulus, Delle Chiaje, whilst his figure indicates Nerine fuliosa.

The second British species is Nerine cirratulus, Delle Chi je, which has a wide distribution on both east and west coasts and extends to the Mediterrancan. The head is a a ut ly pointed anteriorly, the central processes passing backward to end in the median tentacle. The median ridge is supported by the buccal segment on each side, so that the snout appears to be trilobed. The ey es are four and small, the anterior pair wider apart; situated in front of the oceipital t-ntacle. The body is $6-8$ inches in length, and posteriorly terminates in a crenate anus. The branchise commence on the second foot, and the dorsal lamella is attached to the out $r$ edge in front. At fisst, $e$. g. from the
 becomes single and hatchet-shaped and is fixed only to the base of the branchia. At the loth font the long, almost filiform branchia projects upward, the coil of the included ressel leaving only $l_{6}$ of the length free. Nearly a third of the outer border is oceuphid by the upper flap of the disision, and the free papilla at the tip projects upward in addition. The. strong yet fincly tapered bristles extend obliquely upward beyond the edge of the flap, and only traces of wings are present. The tips of the shorter bristles form a regular scries nearer the edge of the flap, and the broader and less tapered extremities of these show indications of wings. All are minutely dotted, as mentioned by De St. Joseph. The flap of the inferior division forms an irregular semicircle, shorter from above downward than the superior, but projecting further outward. The dotted bristles also form two series, riz. a lower group with finely tapered tips and a shorter series with slightly winged tips; the upward slope of these bristles being luss than in the case of the dorsal. Little change occurs at the 25 th foot except the increase of the iuferior lamella, the subulate condition of the branchia, and the more slender bristles. The hooks have a bold upward curre toward the end of the shaft, then the diminished tip beuds backward and ends in a small, blunt fang with a spike on the cromn, the whole guarded by mings. At the 70th foot bristles still occupy the upper division, so that the sonthern forms. from which Mesmil (drew $u_{i}$ ) his deseription,
differ considerably from the northern. The diminution of the branchia gocs on posteriorly with the separation of the lamella behind the bristles. Mesnil includes under this form Malacoceros lonyirostris of De Quatrefuges, Nerine ayilis, Verrill, and Nerine heteropoda, Webster.

The third species is Scolecolepis vulyaris, Johnston, which has a truncate head with a frontal tentacle at each side, the anterior border forming the base of a triangle, the apex of which goes to an adherent occipital tentacle. The long palpi are pale, marked externally by whitish bars with the zigzag blood-vessels. The eyes as a rule are absent in the preparations. The body is $3-4$ inches long, slightly narrowed in front, and tapering posteriorly to the vint, which has 8 cirri (De Nt. Joseph gives 20-39 and Mesnil 16). The first foot carries a distinct though small branchia. The bristles of the upper division form a fan and are in two sections, the dorsal much longer, more slender and more finely tapered, and an inferior group of shorter bristles also with finely tapered tip:. The bristles of the fan-like ventral row are similar in structure, but shorter. All lie in front of the lamelle. At the loth foot the inferior lamella is vertically elongated, its upper edge embracing the branchia, whilst its inferior forms a rounded lobe ventrally. The upper group of gold $n$ bristles still point dorsally, but they are shorter. The long lower bristle-row is curved backward. The lamella of the inferior division is short and ha ch t-shaped. Beneath the fregoing is a small lamella, probably homol gous with the papilla present in Nerine. No noteworthy change occurs in the 25th foot, except the increase of the ventral lamella, and the same may be said as far as the 50th. About the 50th, however, the elongation of the ventral lamella is conspicuous, and a scries of long, wing hooks appear in this division. These have stout curved shafts, a strong and sharp main fang, and two wellmarked spikes on the crown. Short bristles accompany the hooks, and about three are prominent ventrally. De St. Joseph found that the hooks appeared between tice 30th and 52 nd, whilst llesnil gives from the 35 th to the 37 th. Except that a diminution in the general size of the feet occurs, the arrangement is similar at the l00th foot, but the dorsal bristles are considerably longer and more slender. The branchia remains fairly large, and the ventral hooks retain the same type as in front and are accompanied by the short bristles. In life the lamellæ of the feet as well as the branchiæ, which meet those of the opposite side in front,
are museular, and perform various movements. Mesnil could not satisfy himself as to the identity of Johnston's Nerine rulyaris with De Quatreface's Mulacoceros vulyaris vel Scolecolepis yirereli. He points out that what was sent to him from Ueligoland as Xerine vulyaris, Johnston, pertains to Scolecolepis fuliginosa, Claparede. Ehrenbam, he states, considered the Aomis wayneri of Lemekart as identioal with the supposed Nerine culyeris, and Mesnil thought Ci,holoranchus ciiatus, Keferstein, a distinct form, a view not now held.

The fourth British speeies is Eonlecolopsis fuliginosus, Chapariede, in which the head in lateral view is more pointed than in scolecolepis rulyaris, and in. front has a median cleft. The constriction behind the broad bave of the frontal tentacles is more marked. A eram-enloured patels oceurs on the prostomium, witi black pigment on that recrion and on the dorsum as well as on carlo side of the month. The palpi have dark bands. The body is about :3 inches long, smaller, as a rule, than scolecoliphis ro'guris. with longer branchice anterionly, and it tapers a little in front, but much more ponteriorly, where it ensls in a vent with of flattened cirri. The segments numerous- 150 to 160 .

The first foot carries a larger branchia than in S. culyaris, and the superior lamella is narrower and the tip more acute, whilst the infenior lamella is aloo narrower and more prominent. The bristles are simblar, but more delicate. At the loth foot the branchia is a long, richly ciliated process, the up|er lamella is hatchet-shaped, pointed and free superiorly, the inferior lamelia being capstan-shaped. The long briztles at the upper edge of the dorsal tult have narrow wings, and the shorter forms, dorsally and ventrally, are finely tapered. The bianchia and superior lameila diminish before the 50th foot, about which foot three or four winged hooks appear in the rentral division. These hooks differ from those of Scolecolepis vulyaris in the larger angle made by the main fang with the neek, in its rather l!unt tip, and in the presence of only a single spine on the crown. The ventral hooks and assoriated short bri-tles continue to the posterior end. This form is not uncommon in the south. Mesmil makes two varieties, viz. va: microchecta from Naples, and macrocheta trom the Channel, and further two subdivisions, riz. minor and majoi, but such distinctions are mainly of interest in demoustrating the variability of the species.

The fifth member of the group is Ecolecolejuis (Laonice)
cirrata, Sars, a northern form which extends from Shetland to the S.W. of Ireland, and abroad to Grecnland, Norway, and Canada. The broad auterior edge of the short head is smoothly rounded, or in some slightly bilobed. A somewhat triangular ridge, with the base in front, passes ba kward and cuds in a point postcriorly, from the apex of which a small subulate tentacle springs. Two eyes are present, one on each side of the ridge in front of the tentacle. A lamella occurs at the base of the long tapering palpi. The body is about 1-2 inches in length, and is little tapered in front, so that it has a truncated aspect. It is romuded dorsally and deeply grooved ventrally from end to end. The first foot bears a branchia and a large hatchet-shaped lamella, with a conical end superiorly and a somewhat straight margin inferiorly. The ventral lamella is nerly as large, bluntly conical sup-riorly, and curving to a sharp angle inferiorly. The dorsal bristles are capillary, the long tuft being superior, the shorter inferior. The branchiæe continue of considerable size to the 25 th foot, the great dorsal lamella remaining nearly as at the loth foot and is almost reniform. The ventral lamella is slipper-shaped, the broad end being uppermost, and both are free. The winged hooks appear about this (25th) foot, have a slight dilatation of the shaft above the backward curve, then gradually diminish to the throat, from which the main fang comes off at a little more than a right angle, and a single spike occurs on the crown. Tiwo slender capillary bristles are below the hooks. The bristles become very long and attenuate posteriorly, and wings are not evident. Not a single British example is complete, and few go beyond the 25 th foot.

The British species of the genus Spio have hitherto been iuvolved in considerable obscurity, for though three are described by Dr. Johnston in the Catalogue of the British Museum, it is by no means easy to identify them. Only two are entered by Malmgren as occurring in northern waters, viz. Spio filicornis, O. Fabr., and Spin seticonnis, O. Fabr., both of which were known to O. Fabricius, who founded the genus for annelids with two long tentacles. Dr. Johnston in 1838 placed Nerine and Leucodlore under the same head. (Ersted separated the genera Nerine and Spio by the form of the dorsal lamellae; whilst Claparede showed that this distinction was artificial. Mesnil, again, thinks that Malmgren complicated the question by reviving the generic name Scolecolepis and undid the advance made by Claparede, a view which cannot now be hild. Yet he affirms that Malmgren
conserved the genus Sppio without definitely defining it, and described under the name spio filicernis, O. Fabr., a species which he (Mesnil) has demonstrated to be very near his Spio martinensis, and he doubts if Malmgren's form is that of Fabricius, thongh the figure pertains to the same genns. He dows not accept Levinsen's inclusion of the ge us Nerine of Johnston under spio. He does not, in short, know any species falling within the deseription of the two species of Fabricius as entered by O. F. Müller.

For the present purposes the genus Spio may be characterised, after Me-nil, as having a prostomium without frontal tentacles; branchise from the first setigerous segment to the end; anus surromoded by cirri ; always two rows of bristles in each division ; and after a certain secment (Xth to 15 th) the posterior row is formed by winged hooks. The first species is Syio filicornis, O. Fabr., which has a snout somewhat like that of Polydura on a large scale, or akin to that of Pygospio, with a blunt bifid med an rostrum and a bulging process of the buccal segment on cach side. Two or three minute eyes oceur on cach side of the median ridge posteriorly. The median process passes from the tup of the snont backward to end in a conical papilla. The body is ${ }^{2}-3$ inches in leng h, broad and sca:cely tapered in front, but gradually diminishing to t.e moderately flender posterior end, which has two thicker cirm dorsally and two more slender cirri ventrally. The segments range from 60 to 80. The ligulate branchise occur on all the bristied segments. The superior lamella of the loth foot is blunty rounded dorsally and slopes obliquely to the wide notch inferiorly. The ventral lame!la is more or less semicircular. The bristles of the upper division form a wide tuft ; the longest superiorly, and all are curved backward and winge.t. The rentral bristles are somewhat shorter, but similarly tapered, and some of the lower forms present a slight dilatation in the winged region. The type of bristle rapidly changes, for at the 14 th foot, or sooner, a row of hooks appears in the rentral series, with finely tapered short bristles in frout, and a iew winged bristles inferiorly. The upper lamella gradually diminishes, and still more the inferior, so that the setigerous process becomes prominent, and a group of bristles at the ventral edge of the inferior division becomes modifiedeach being curved, flattened, and iurnished with a hook or a probe-tip. The winged hooks have straight shafts, which increase in bulk superiorly, then curve back ward and slightly dilate before the contraction at the throat. The strong alid
sharp main fang comes off nearly at a right angle and the crown has a single sharp spike. This form was dredged in \& fathoms in Bressay Sound. Mesnil's Spio martinensis *, which he hints may yet be linked on to Spio filicornis, O. Fabr., differs in the form of the head, since it has no fissure in front, but the author's drawings perhaps need more definition. Moreover, he mentions no occipital tentacle. The number of segments, the size, and the gencral structure of the tail, feet (from the lst backward), and bristles agree, yet in the British form the latter are not punctated, a feature of moment, for only longitudinal striæ are visible even in the inferior ventral.

Spio seticornis, Fabr., has a head produced anteriorly into a rostrum, with two small frontal tentacles, the central region supported by the buccal segment on each side. It is about an inch in length, little tapered anteriorly, and gradually diminished posteriorly. The branchir commence on the first segment aud apparently continue to the posterior end. They seem to be conspicuous about the middle of the body. The foot has a narrow and prominent superior lamella in front and a small conical lower lamella. The former diminishes posteriorly and the latter becomes flattened out as a narrow rim. The bristles present a long dorsal group and a shorter lower group in the superior division, and a similar short group in the ventral division anteriorly; but at the 8th bristled segment the place of the latter is taken by winged hooks, the main fang of which comes off at a large angle from the neck and is not very acutely pointed, the rounded crown bearing a single spike.

This differs from the previous form in so far as the hooks appear before the loth bristled segment, probably at the 8th. Thus at the 5th foot the branchia is well developed, whilst the upper lamella passes outward and upward as a broad conical flap, and the bristles form a diminnshing series from above downward. The inferior lamella is small, forming a short blunt cone pointing below the setigerous process. At the loth foot the branchia is larger and appareutly flatteued, the upper free edge above the superior lamella is shorter. The superior lamella is small at the 25 th foot, but the branchia remains large; it becomes less at the 50th foot. It is difficult to say what the S'pio seticornis, Faur., of Cunningham and Ramage $\dagger$ is. Mesnil thinks it has

[^23]the characters of Pygospio elegens, but this is doubtful. Two thick anal cirri occur posteriorly.

A softened fragment from the deeper water off St. Andrews Bay appears to pertain to a distinct form which may provisionally be termed $\mathbb{S}^{\prime} p i o$ D). It is about 2 inches in length and with subulate branchix from end to end. Two eles occur anterionly. The dorsal division of the foot has long tufts of fincly tapered capillary bristles, and the ventral appear to have a similar character, though this was not observed in situ. Posteriorly the dorsal bristles increase much in length. Some of the tufts show also a shonter series of stronger bristles with a distinct hook at the point, and in some groups in the pulpy preparations no other form occurs. It may be that the shorter hooked forms represent the ventral series posteriorly.

A small form procured between tide-marks, St. Peter Port, Gucrnsey, may be related to Sipir meczuikorianus * of Claparede or to the spion ulanticus of Langerhans $\dagger$, since, so far as can be made out, the dorsal lamella does not fuse with the branchia, which seems to extend firom the second segment almost to the pusterior end. Claparede, however, gives his form only two anal cirri, wheneas Langerhaus states that there are four, the number prenent in the form under consideration, and they are similar to those of Pygospio eleguns. The head somewhat resembles that of the species just mentioned, having two rounded bosses in front, apparently better defined than in Pyyospin. The median ridge continnes backward to the first segment or a little further. On each side, about the middle of the head, is a conspicuous black eye, and a trace of a second pair a little behind. The tentacles are absent. The body is comparatively small, about half an inch in length, somewhat i, road and flattened in front and then slightly tapering to the shout, more gently tapered and rounded posteriorly, the tail terminating iu a minute seyment with 4 somewhat short conical cirri as in Pyyospio. In the anterior segments the dorsal lamella, as riewed from above, appears to be filiform-sloping obliquely backward behind the bristles. Winged hooks occur ventrally on the $\delta$ th foot and continue to the posterior end. The shaft of the hook dilates from the narrow proximal end nearly to the wings, curves backward below these, coutinues

[^24]of nearly the same diameter almost to the neck, which is narrowed, but not much. 'The main fang comes off nearly at a right angle and is short and sharp, a single spike only occurring on the crown, and thus agreeing with the form described by Langerhans. The bristles follow the typical arrangement.
A. Spio (G) from the decper water off St. Andrews Bay is characterized by the rounded or bluntly pointed snout, the mouth opening a short distance behind the tip. The two tentacles are of modorate length and adtacre firmly to the snout. At least one eye occurs on each side at the immer base of the tentacle. The body is about half an inch in length, somewhat rapidly tapered anteriorly, and more gently posteriorly, where it ends with cirri (only one of which is present). The dorsal surface is somewhat flattened, the ventral rounded. No branchise are visible. The dorsal lamellie are much developed and foliaceous in front, especially the third. Winged hooks make their appearance about the 15th bristled segment; they are slender, slightly tapered after the backward curve to the throat, have a main fang and a single spike on the crown. The dorsal Jamelle diminish greatly after the 15 th scgment, and in the posterior half form small conical processes behind the setigerous papilla. The ventral division in the same recrion is represented by the hook-papilla. The dorsal bristles are capillary, finely tapered, and curved backward. Pusteriorly they greatly increase in length and are very slender.

A species swarming in sand near low-water mark, St. Andrews, and also dredged in 2 fathoms of Symbister Harbour, Shetland, has been provisionally named Spio gattyi*. The head terminates anteriorly in a rounded point-the centre of a cone formed by the buceal serment. A minute black eye occurs on each side of the medtan ridge, which ends in an occipital papilla or tentacle posteriorly. The body is about an inch in length, proportionally short and stout, a little tapered anteriorly, and more so posteriorly, where it cuds in two broadly ovate cirri. The branchire are conspicuons from the lit foot to the end. The dorsal lamella of the Ist fort is elongate-oroid, with about a third of the dorsal folge free, the rest fused to the base of the branchia, the lower margin trending gently to the body-wall. The dorsal bristles are of moderate length, curved hipward and slightly

[^25]hackward, fincly tapered, the upper series long and slender. The ventral lamella is a prominent, obtusely ovate process. By-and-by the superios lamella is flattoned externally and less free superiorly, and the rentral lamella assumes a rhomboidal outline-rounded at the inferior angle. The winged hooks commence in the ventral division abont the 13 th foot along with the delicate bristles, and they show a main fang with a spike on the crown. The lamellie increase in size immeriately before the 50th foot, the wing hooks to the number of 9 oceupying nearly the entire length of the ventral lamellæ.

A small form not hitherto recorded, thongh it has long been known in Britain, is I!!!!ospio clegans, Claparèle *, which occurs abmodantly in sandy tubes in fissures of rocks and similar localities in varions parts of the kingdom. The head is bluntly bifid, with a median ridge rumning backward to the second segment. The eyes are 2, 4, or 6, situated on the ridge or behind the middle of the ridge and between the tentacles, which are very lone and attemuate. The body is very slender and elongate-of a dull yellowish colour with a tint of orange, the anterior third being reddish from the blood-vesels. The segments number from 10-60. The first twelve bristled segments are narrower than the succeeding. The branchia appears on the 13 th segment, and to its outer border the somewhat crenate lamella is fuserl. From 19 to 2.5 pairs of branchice are larecly developed, with conspicuous cilia in a row aloner the median anterior region, the rows of opposite sides being connected by an intermediate line of these organs. The largest branchise are about the posterior third of the series, and they appear to differ from the French examples, which have the branchise, aceording to Mesnil, equally developed throughont, and that, moreover, their number is usually 8 , though they may reach 23. Posteriorly the borly terminates in 4 small whitish conical processes which are not ciliated. Anteriorly the feet have conical dorsal lamellie and smaller conical rentral lamelle, but the latter sonn diminish. The upper dorsal bristles are long and finely tapered, whilst the lomer and shorter have broader tips with finely tapered ends. The wider ventral forms occur on the 3rd foot, as indicated by Mesnil. All the bristles are dotted and curve backward. This type of foot extends only to the 7 th, for the 8th has its ventral bristles replaced by winged hooks, about 4 of which occur on each

[^26]foot. The wings are short and broad, expanded and smoothly rounded at the free end. The shaft has a forward curve distally, then it bends backward below the wings, and slightly diminishes at the throat, from which a short sharp main fang passes off at little more than a right angle, and with a single prominent spike on the crown. Po-teriorly the dorsal bristles greatly increase in length and slenderness, stretching upward and outward as a hair-like tuft, whilst the superior lamella is represented by a small conical papilla above their base. The hooks occupy the same relative position, but the number is greater, viz about 7 , and a slight rim indicates the ventral lamella.

Another form very common amongst sand near low-water mark at St. Andrews is Spiophanes brmbly, Claparède *. In this the head has two short frontal tentacles, from which a median elevation passes backward to end in a small conical peak or eminence. The two palpi are of moderate size, contain blood-vessels, and are frequently coiled. A small eye-speck occurs postcriorly on each side of the median ridge near the peak, and in the preparations are raised, with the ridge, above the general level. An anterior pair, a little wider apart, lies in front of them. The body is about 3 inches in length, very litule tapered anteriorly, and much more so posteriorls, where it ends in a wide rent with crenate lips and two short ventral cirri. Many specimens have reproduced tails, for the species is remarkable for its fragility. The dorsum is somewhat flattened anteriorly, rounded throughout the rest of its extent, and marked ventrally by a median band, which, when it comes to the vent, splits, a limb curving upward on each side to join the dorsal band, and it may be indicating the junction of the ventral with the dorsal vessel. A median and two lateral brownish lines occur on the dorsum behind the head, but they pass only a short distance backward. The sides are vascular anteriorly, then of a pale brownish hue, thereafter orange from the colour of the gut. The ventral surface is pale, though the gut is visible.

The 1st foot has dorsally a subulate or narrow lanceolate lamella (cirrus) which has been shifted inward, so that it resembles a branchia. The dorsal bristles are very long and slender, with hair-like tips and with no evident wings. They spring from a conical setigerous process, also carried inward on the dorsum. The ventral bristles of this foot are shorter

[^27]but similarly filiform at the tip. In addition two much thicker bristles, winged at the tip, resemble modified hooks, since they end in a small claw-like tip. These hook-like bristles apparently perform a special function in the tubicolous habits of the species, just as the homologous organs of Sclerocheilus do. Either considerable variation occurs or Mesnil's figure of these organs is at fault, for he shows and describes them as having a simple tapering tip and winged in the ordinary way, whereas the specimens from St. Andrews lave the tips specially differentiated and the wing adjusted like that of a hook.

The dorsal lamella moves gradually to the dorso-lateral recrion, and the foot at the fith bristled segment presents a massire lateral enlargement. This is more clearly shown at the loth foot, the domal lamella being now comsilerably shorter, though still subulate, and the hase is broad. The dorsal bristles can be differentiated into a longer upperseries and a shorter and stonter lower series, as usual in the group, and they spread in a fan-like manner in front of the dorsal lamella. 'The ventral lamella has been modified into a great lateral mass which prasees upword to the base of the dorsal lamella. The rentral bristles are short and stout, the lower forms distinctly curved backward at the tip, which is minutely dotted or mottled as well as winged, and appears, indeed, to be the special bristle figuted by Mesmil-so different from the two peculiar hook-like bristles of the ventral division of the first segment. The laterally cularged feet seem to be most prominent from the 4 th to the $1-4 t h$. In its progress backward the dorsal lamella or cirrus becomes less and presents a ventral enlargement, which is very maricel, for instance, at the 15 the segment, the massise base being in contrast with the slender distal process. Moreover, the winged hooks appear in the ventral division of this foot as a row of four, and beneath them is a single strong curved bristle or two with the dutted or mottled tip, which points downard. The feet considerably diminish from the 20 oth to the 30th. Thus at the 25th the shape of the dorsal cirrus or lamella is like that of a leg of muttom, the shank formed by the tapering cirrus it-elf. The doral bristles are still arranged in a fan-like tuft, the upper being the larger, and a line of powerful cilia runs from the fuot inward on the dorsum. The space betwern the divisions is much reduced, and below the hooks are two of the powerful, sliphtly curved bristles which have the dotted distal regions and sharp points. The wiaged hooks are proportionally small, have a slightly curved and shary main fang, coming off nearly at a iight
angle from the throat, and with a small spike on the crown. At the 30th foot at least a dozen of these organs project from the surface.

Just in front of the tail the dorsal cirrus is moderately long and subulate, and occasionally it shows a basal conlargement. The dorsal bristles project for a third of their length beyond the tip of the cirrus. The region between the divisions of the foot is convex, and below the row of 7 or 8 hooks 1 or $\because$ curved bristles project. The convexity of the curve is outward.

Formerly, in consonance with the Catalogne of the British Museum, it was supposed that only one species of Polydora occurred in British watere, but more extended examination shows that at least five species are found in our scas besides Polydora caca, Ersted, entered in the fauna of Plymouth, but which has not yet been examined at St. Andrews. The genus (founded by Bosc) was first clearly described by Claparede, who, however, inchded it under the Ariciide. The first species, Folydora cillata. Johnston, has the prostomium elevated and termiuatiug aateriorly in two rounded lobes with a median notch, the ridge passing backward to the Brd segment. Four black eyes are on the ridge, and dark pigment occurs at its sides and in the furrows of the first fuur segments. The body is largest in the anterior third, flattenced dorsally and rounded ventrally, tapered a little anteriorly and more distinctly posterionly, where it ends in a cup-like process with a dorsal notch. 'The segments are from 60-75 in number. The branchia commence on the 7 th foot and their number ranges from 22 to 31 . Thus they differ from Mesnil's form of $P$. ciliata. The first foot has a dorsal lamella but no bristles, but the latter occur throughout the rest of the body. The fifth bristled segment has large hook-like bristles, the tips are curved, more or less acute, and have a small spur on the neck. This form is very widely distributed in European waters.

The second is Po'ydora flata, Claparede, which extends from Shetland to the Channel Islands and is common in the Mediterranean. The bifid prostomium is usually longer than in Polydora ciliata and the divergent processes more distinct. A little pigment occurs on each side of the prostomium in front. Eyes are not visible in the preparations. The median ridge of the snout reaches the fourth bristled segment. The borly is of considerable proportional size (2 inches or more in length) in contaast with $l^{\prime}$. ciliate, but of similar con-

[^28]formation. The terminal coudal process has an even (continuous) rim. The first foot is peculiar in having bristles in its dorsal division, which presents a rounded lamella with a setigerons process in front and a small tuft of tapering bristles slightly curred backward in situ. The ventral dirision has a smilar thongh somewhat broader lamella, in front of which is a conspictons eronp of longer upper and shorter lower bristles, the latier having distinct traces of wings. The second, third, and fourth feet have completely formed dorsal and ventral divisions. The ith semment has minute tufte of dorsal and rentral bristles, as in other forms, besides the great hook-like brintles mhich have the concarity of the tips dircoed harkward, and which are arranged in a col re. In the ordinary condition the shaft emlarges from the base upward to the middle, then slight? dimmishes to the tip, which forms a icrer-like hook with a concarity posteriorly and an exearation in fromt. The foregome hooklike hristes are aceompanied by a series of speap-shaped mristes. In the developing hook the distal curwe is wery marked, and a small shoulder appears at the bave of the roncatity in front, whilst a lateral dimple and cleration and a differentiation at the commencement of the teminal curve are evidont. In frontal riew, as Mennil sliows, the distal region is likewise difierentiated. The winged hooks commonce in the rentral disision of the $\boldsymbol{r}$ th bristled segment. Each dilates a rery little above the base and has a marked forward curse througlont the greater part of its length, then bends backward and dimini-hes to the neck. 'The main fang eomes off at a considerable angle to the neck and is sharp, but the spike out the cown has a small angle with the fang. The dorsal bristles become extremely slen eer posteriorly, though of considerable length. Morenter, handles of bristles even more slender than the forequing oceur in each foot posteriorly and they somew hat resemble linear ergstals, being perfectly straight and slightly tapered at each end. The function of these is muknown. Alesuil states they are extremely caducous, and do not occur in from of the 80th bristled segment. The bacillary ponches seem to contain only granules somewhat larger than in Daselona. The branchire commence on the sth si ement, attain their maximum a few segmonts behind, and then they gradually (liminish, the total mumber being about 35-10.

A thind species appears to approach the Polydora quadrilubutu of Jacobi*. The head lias smaller prustomial lobes

* Anat. histolog. Tntersuch. der Polydoren der Kieler Bucht. Wissenfels, 1883, p. G, Taf. i. © ii.
than Poiydora flaca and the median ridge goes backward to the 4 th segment. The snout differs from most of the other forms in its conical outline, since the peristomial supports taper anteriorly. Jacobi describes and figures four eyes on the median ridge between the tentacles, though they are frequently absent. The arrangement of the bristles in the first four segments appears to be typical, though they are somewhat shorter than in Polydlora cilista or in P. flere, and the groups in the dorsal division are clearly differentiated. The fifth foot is distinguished by the large size and conis:icuous condition of the dorsal capillary bristles (Pl. V. fig. 3), for the expanded distal region is bent at an angle to the shaft, and the tapered tip is again curved ; thes the aspect is that of a pointed bill-hook. The great hook-like bristles (P]. V. fig. 2) dilate from the base upward fully two-thirds of their length, then slightly diminish to the throat, from which a short distal region comes off at con-iderably more than a right angle and ends in a bifil truncated tip. ©Six or sereu oceur on each side, but the tips of only four or five project from the surface. Jacobi * de-eribes and figures those of his I'olydora quadrilobatu as endiag bluatly with a right and left spur and a thin guard or wing. The latter, however, was not risible in this example, but may have been abrades. 'The ventral tuft is considerably smaller than the dorsal, but the type of bristle is maintained on a diminished scale.

So far as could be ascertained in the fragmentary form, the branchise commence on the 7 th bristled segment, and the hooks, which do not materially differ from those of Lolydore ciliatu, on the 7 th segment. Jacobi represents the anal fumuel as 4 -lobed, but it was not present in the British specimens.

Langerhans $\dagger$ describes Po $y$ didora armatu, from Madeira, as having in the ath segment two or three large hook-like bristles with trifid tips, but his figure shows a blunt, cursed tip deeply cleft and winged, the outline being very different from Jacobi's. The prostomium is bitid, and the peristomial lobes are also blunt in front. The branchie occur from the 7 th to the 12 th segment. Moreover, in the last five or six segmeuts brownish, stiff, straight, tapering bristles are present, thus differing, he observes, from Keferstein's $l$. ciliata, with which the branchise agrec. The anal funmel has a doisal and a ventral hiatus. If tiguris can be relied on, the tips of the large bristle-like hooks of the 5th segment as well as the anal fumel differ from Jarobiis speriec, and

[^29]('arazzi * compares the former with the perlicellaria of Echinoderms.

The fourth species, viz. I'olyduru carazzi, soems to be new, the prostomium anteriorly forming a smoothly romded procoss, and thus characteristically diftering from any of the forerging. This proeess projects very little in front of the romuded lobes of the peristomium at the sides. The median ridge is slighty contracted behind the process, and passing backward terminates at the fonth bristed argment. The mouth opens on the rentral surface as a long triangle with a prominent lip on each side. So syes are visible in the spinit-preprations and mo pigment, buit it may be different in the lising esamples. The body, of which only the anterior $2(j$ segment- remain, tapers from the thl segment forward, the rest having nearly the same diameter; and it is a feature that the sith bristhd secgment is fully in a line with the others, its anfero-postexior diameter, as usual, being greater than that of the segments adjoining. The first foot has both a dorsal and a rentral lamella, but omly a tuft of ventral bristles, the tips being directenl rather ontward than backward, the convesity of the cume, howewer, being forward. They are shorter than those immediately following. The 2nd, Brd, and the feet wifer no feature of note. The fifth foot is musually prominent, and bears dorsally a strong tuft of capillary l,ristles, the flattened, winged, and rather short tips of ihich curve somewhat abruptly backward. The great hook-like bristles have the points of the main fans directed backward and slightly upward, and each consists of a broad flattencl shaft (Pl. V. firs. 4 (5) 5), which dilates from the hase to the distal third, where a gentle curve backward and a little diminution towards the throat ocour: but whilst the imer outline is eren, the onter shows a slight projection rather below the throat, which is by means narrow. The strong main fang comes off at a little more than a right angle, and the tip is not very acute. Moreover, the crown of the fang secms to have the upper edge flattened and prominent on each side, whilst distally a comb-like crest with a serrated edge curves from the back of the crown almost to the point of the fang, so that uncinus crista-galli might be an appropriate name for such a hook. Indications of strix which slope from behiud forward and upward show that this crest is an aggregate of spines. Only a few bristles occur in the rentral tuft of this serement. The Gth bristled

[^30]segment has lamellie and dorsal and rentral bristles like the 4 th, and winged hooks commence on the ventral division of the 7 th, where also the branchire originate. The winged hooks (Pl. V. fig. 6) do not offer any diagnostic feature except their small size, a single spur occurring on the crown above the great fang. In contrast with Polydoria flava, the lamellæ of the feet generally and the bristles are shorter, whilst the hooks project similarly in both. The species seems, so far as known, to be sparingly distributed.

The Polydora hamota of Langerhans* also possesses a smoothly rounded prostomium, and the sides of the peristomium form a blunt cone. The great hook-like bistles of the 5 th segment, however, somewhat resemble those of Polydora flaca, and thus differ from the foreging. The rentral hooks, moreover, have a brown belt on the neck, and the last 30 segments, or thereabout, have hook-like bristles, after the manner of Polydora hoplure, whilst the anal funmel is t-lobed-all points of divergence from the preceding form.

The fifth and last of the series is Polydor"e hoplura, Claparede, which extends from the Outer Heboides to Plymonth, and is also fomud on the east coast at sit. Andrews. The head is similar to that of I'olyd wa ciliatu, except in the absence of black pigment in the preparations. The prostomum anteriorly has a median noteh and two romnded lateral regions. The arramgement and shape of the lamellie and bristles of the first four bristled segments are like those of $P^{\prime}$. ciliata. The fifth segment has hook-like bristles which are distinguished at first sight from those of $P$. ciliula by the parallel arrangement of the tips in situ-a feature due to their more uniform diameter,-by their peculiarly curved and by no means sharp tips, and by the position and size of the lateral spur at the neek. The branchire and winged hooks commence on the 7 th segment, the hooks haring a somewhat long main fang coming off nearly at a right augle with a single spur abore. 'The feature most diagnostic of this species, viz. the hook-like bristles of the last 15 seyments, is absent in the majority of the imperfect examples, but where the caudal region is present the recrion ocenpied by the hooks seems to be distinguished by the diminution of the prominent tufts of bristles characteristic of the reyion in front. The strongly curved and sharp hook-like bristles
are probably comected with the special functions of the region, which may reguire a hook of a different type from the ordinary winged form.

Some place the next form, viz. Magelonn ponvilicornis, leritz Miiller, under a special family, but for the present it may be included, as formerty, mader the Spiomide. The head (prostomium) is a large, flattened, and sontewhat oroid muscular process, with chitinoms basement-tiswe, marked marginal! ly anastomoning vewels and forming a roof 10 the peristomial soment bencath it. The mouth epens rentrally, and the proborecis is extruled as a pinkish mush-mom-shaped omsan. The tentackes are remarkably long (2-3) inches), with large anhewive papillis on the distal two1hirds, and mon-raducons. Tonchers of dark pigment occur an bars on them. The booly is from 4-finches in length, apparently of two well-marked remions-the anterior short, consisting of 8 scoments, and the posterior of more than 100 ; hut the pecouliar enh arement perhaps indicates a third region. The boty is somewhat quatrangular in section theonghomt. The first region (of 8 segments) is narrowed behiod and marked by a domal and a rentral longitu imal hand, whilst the Sth sequent is remarhably narmw. The thied region is anteriorly of greater diameter than the first, continues of considerable breadth for some di-tance, and then gradually tapers to the tail, which ends in a rounded border hasing the anms within it, and with a shopt cirrus om cach side. The lateral regions of the greater part of the third division of the body are modified into processes with peculiar comvoluted organs componed of the cuticle, hypoderm, and basement-tissue.

Tre dorsal lamelle of the first division are scoop-shaped, and the ventral are similar thongh smaller. The bristles of the region are capillary. The bristles of the gth segment are shaped like a mace with a process at the tip, and differ from all the others as do the lamellie. The thied or posturion region has on each foot a row of winged hooks dorsally and another rentrally at the edge of the quatrongular borly, whi'st the somewhat ovate lamellie are between them. The species ranges from Brazil to Britain.

The interesting Pacilochetus sempens of Dr. Allen **, from Plemonth, probably fomes near Disoma and scalitireyma. The pelagie pos-larval tyes oecur frequently at st. Andrew: yet no adult has ever been found there.

[^31]
## 3. On the Spionide dredged by H.11.S. 'Popcunine' in 1869 and 1870.

Besides the widely distributed Scolecolepis cirrata of Sars, east of Cape de Gatte, in 16 to 60 fathoms, a form apparently falling under the gems Nomindes of Mesnil, and which may be termed $N$. lamellata, was dredqed in the expedition of $18 \%()$ in Tangiers Bay at a depth of 35 fathoms. Only the anterior region is present. The head (P'l. V. fig. 7) forms an even transverse margin in front, with a short blunt tentacle at cach angle, and from the centre a short elerated reqion proceeds backward, to end in a small process which is pointed posteriorly like an adliercut tentacle. Minute eyes seem to be present on each side of the latter, bat the condition of the specimen renders aceurate determination difficult. The whole region is thus unusually short, and the proboscis is thrust out as a short cylinder with a crenate margin. The body is flattened, slightly and abruptly tapered anteriorly, and with a median band ventrally. The serments are narrow and uumerous. The lst foot carries a subulate branchia a:nd a large lancolate lancha projecting freely upward nearly as far as the hanchia. The dorsal bristles are very slender, long, and finely tapered, and they have the normal position characteristic of the family. The ventral division also has a lanceolate process, and the bristles are long and slender. From the form of the body the bristles and lamelie ocoupy the dorso-lateral edge, so that the branchiee, which re dily fall off, pass tramsverse'y inward over the flattened dorsim. At the 1Oth foot the branchia is well developed, thongh sti! subulate, and the dorsal lamella forms a large lanceolate flap directed upward and inward. The bristles (Pl. VI. figs. 1 \& 2 : $)$, both dorsal and ventral, are long and slender in mass, and Iave a dull golden colour. The ventral lamella is now a broad, almost scmicircular flap, with a tendency to a peak inferiorly. The bristles (Pl. VI. fig. 3) are in two groups, viz. fincly tapered forms which stretch outward aloug the lamella, and a ventral series of shorter, broader bristles overlapping the former, like those seen in a Scolecolepis from Bressay Sound ; but their tips are acute, not probe-pointed.

The branchia remains subulate at the 25th foot (Pl. VI. fig. 4) and stretches beyond the elongated upper lamella, which is acutely lancolate superiorly, its outer edge boing comparatively even till it curves inward inferoorly. The iontral lamella forms a blunt flap with the bristles in the sroups formerly indicated. The branchia is still rather loner
and subulate at the 50th fors, and the upper lamella is prominent and rounded inferiorly, whilst superiorly it is acutely lanceolate. The upper bristles of the dorsal series are long, slender and finely tapered. A notchnow scparates the two divisions of the foot. The ventral lamella is aloo prominent and rounded. gencrally with a short peak. The modified bristles ventrally show a sharp and slightly hooked point (Pl. V. fig. Si, which under a high power is slightly dotted. No wings are visible in either dorsal or ventral bristles.

A fragmentary corolecolepis (I), dredged in 3.5 fathoms amidst grevish sand, stones, and onze in the " Poreupine' Expedition of is69, shows certain nowel features. The head is short, with a slightly hilobed anterior border, which forms the base of a triangle conding in a hort subulate tentacte posteriorly. No eves are vi-ible in the preparation. A little behind the anterion colge of the smont vemtrally are tun prominent romed d peristomial papilae in front of the momb. The fragmentary boty consists of abont $] 6$ segments, at the posterior eud of which new sergments and a tail are developing. It is flattenced dorsally and eroowed in the median line ecentrally, whikt the sides are flanked hy an extraordinary develomen $t$ of dull golden bristles, which at first -ight makes an approarh to the condition in Emplerosyne. A kind of flap, vertically rlongated, osens immediately behind the suout, but it does not appear to have cither inristle or Dranchia. The firet bristled font carries a branchia and long tufts of hristles dorsally and rentrally; but the condition of the foot negatives a minute deseription. The hrittles are of comparatively great length and strength, are finely tapered, and conform to the usual arrangement in Scolecolepis, the upper of the superior division being longest and rumed upward and backward. No wings are visible. The bristles of the inferior division form a dense group shorter than the superior, and they are curred backward. Focus-ing indseated a margin on each side of the tapered tip, but no distinct wing is visible.

The great development of the superior lamella is soon conspicuous, and at the loth foot (1'l. VI. fig. 9) it forms a large lanccolate crest on the dorsum, the outer or infurior edge being rounded, whilst the imner is acute. Ti.e branchia appears to be subulate and to stretch inward over the dorsum, but all had disappeared during the examination of the minute specimen. The remakably dense, strong, and boldy curved dull golden bristles conre upward and hackward, and namow
wings are evident on the lower and many others in the division. The upper, as usual, are longer and more slender, hut also present indications of wings. The ventral lamell. is separated from the dorsal by a notch with a papilla, and is somewhat capstan-like, only the edges slope to a low cone in the centre. Its bristles curve downward and backward, taper to a fine point, and have narrow wings. Morenver, they are all minutely dotted or dappled, and many of the upper forms show a peculiar mark just below the tip, as if a portion had been scouped out. It is possible that friction may be comnected with this appearance.

The condition of the posterion region is mbunms, but at the 16 th foot the superior lamella is still large and lancenlate, with a rounded outer or inferior margin, and the bristles have rather increased in length. The ventral lamella, however, is smaller and of the form of a short capstan. The bristles are also longer. and a ventral group of 4 or 5 larger, longer, and boldly curved bristles is differentiated, each trpering to a fine point, and the wings are more distuct.

4 form dredged in the 'Poreupine' Erpedition of 1.800 in 4.) fathons off Cape Sagres is distinguished both dersally and laterally by the structure of the suout, which is shaped somewhat like that of ※tcurorepholus, and thas differs from that of Prionospio. It has been termed Kinhergella plumos's, after the distinguished Professor in Stockholm, who has dome so much to adrance our knowledge of the marine anmelids. .

Anteriorly, when riewed from the dorsum (Pl. V. fis. 9), two rether thick, flattened. anterior tentacles are separated by a median papilla, whilat the buccal segment gradually uarrows to the base of a rounded bilobed papilla (like miniature corpora allicantiai) on the dorsum behind. When seen from the front the anterior processes present a double foliate arrangement like the anterior end of certain mollusca, the mouth forming a melian protuberance at the ventral edge. In arrangement of this kind is rare in the group. A kind of collar passes round the body at this region. The mouth opens immediately bencath the median papilla on the snout, and the lower lip, which has a slight cleft in the centre. is prominent, the aperture looking forward rather than ventrally. A projection exists on one side behind the papilla, but nis palpi or tentacles are seen.

[^32]Only a fracment of the anterior region of the booly is present, comprising 17 or 18 bristled segments. It taperis a littic anteriorly and is somewhat flattened both dorsally and veratrally, though the first part of the ventral surface is romeded, and a streak runs along the median line. The whole anterior resion divereses from that of Priomospios.

Belond the bilohed dorsal papilla is a scgment dewod of bristles, mess it is to be reqarded as only an cxtension of the peristomium. Anteriorly it bears the bitobed papilla and the projection on the left side. It is followed by a region provided with 6 or 7 prominent lamella which partly overlap the dorsum, and from the narrowness of the region in front the first two or three approach each other more clomely than those which sticceed.

The first foot carries a broadly lanceolate doreal lobe and a more peointed rentral lobe, the former overlapping the lateral region of the domsom and the latter dieceted olligpely "pward. 'The lorstlos of the domal divicion are cemed backward, taper to a fince puint, and the uppor serio is latere as usual in the group. The rentral briotle hate a similar structure, but are shorter.

The lamelle reach their maximum about the fth or ith foot, projecting above the dorsum as large broadly lanceolate flaps. Moreover, the the fort bears a phomose branchia (Pl. VI. figs. 6 \&゙す) somewhat like a sea-p.n. The base is smooth or slighty crenate, then the pinme appear and continue to the lanceolate apex, towards which they slightly diminish in size. Is mounted, the broadest part of the organ is a little below the tip. The superior lamella is almost like that in Phyllorlore, overhanging the 5 th as a hroadly lanceulate leaf, and with the row of yellow bristhes iu front of it. The rentral lamella is smaller and somewhat conical.

No other branchia occurred in the example, but as the specimen is fragmentary the exact distribution of these organs is unknown. The absence of the long terminal filament so characteristic of Priomospio is noteworthy and does not appear to be due to any injury to the organ.

At the loth foot (Pl. VI. fig. 8) the lamella has become a narrow rim with a bluntly conical free apex, and the bristles are shorter. The rentral lamella is narrow and short, rounded superiorly and inferiorly. One of the rentral rows of bristles is much more slender than the other, with very fine capillary tips. The bristles of the stronger row are broken, so that whether these have winged hooks is uncertain;
hut it is noteworthy that they and the 11th were all evenly broken about the same level.

The lamellie become small before the 16 th or 17 th foot, sinking below the level of the dorsum as inconspicuons conical flaps. So far as observed, the simple dorsal bristles, which present no distinct wings, do not vary, but about the lith foot the rentral series consists of a dense row of winged hooks with rather long shafte, which increase in diameter from below upward, bend backward, and slightly diminish to the throat (PI. V. fig. 10), from which the sharp main fang romes off near'y at a riyht angle, and has three spikes on the crown ahore, the whole, however, quite differing from the hook of Scolecolepis culyaris. The wings are rather short and wide distally.

The specimen is a female, and large ovoid ora with the finely crenate capsule oceurred as far forward as the lst foot.

This form approaches Prionospio in certain respects, such as the plumose branchise and the massive form of the lamellæ.

The Prionospio heterobranchia of Perey Moore*, from Wood's Hole, Massachusetts, bear's certain resemblances in the form of the snout, but the development of the lateral processes (tentacles?) of the snont in Kinbergella difters materially, and the branchice do not seem to possess the terminal filament, whilst the pimæ or filaments of the gill we much shorter in the new form, which is also devoid of the conspicuous eyes. Yet the prostomium in Prionospio heterobranchia tapers to a point posteriorly and the hooks seem to be similar. Finberyella therefore finds its nearest ally in Prionospio.

XXI.—Dissriptions of Sirenten mur S̈mcios and lavimies
 and the I'ransvaal. By H. B. Prestor, F.L.S.
[Plate VII.]
Hayme recently had through my hanls a mmber of lame and freshwater shells from the German Cameroms, and finding among them a number of forms which seem to have hifherte e-caped notice, I venture to describ.s them in the present Paper : at the same time 1 take the opportunity of describing two species of Fiseheriu from songal, collected in that ramim by Colnel M. Messacer, and two species of Achatinas from E. Africa and the Transvaal respectively, as al-o a variety of Achatina variegata, Lk., from IV. Afıica, which, being ćmstant and well-maked in fom, I have thought worthy of a varietal name.

Gibbus (Edentulina) confusa, sp. n. (Fig. 1.)
Shell ovate-elongate, rather laterally compressel, thin, white, somewhat slining, semitransparent, rimate; whonls $5 \frac{1}{2}$, sculptured with very fine oblique transverse lines, very mimutely but closely purctute thronghont, the latter portion it the last whonl somenhat ascending; sutures linear ; colnmella descending nbliquely ahove, excavated below, nutwarily.
triangularly expanded, the expansion bearing a depression in the middle ; parietal wall somewhat cecavated in the region of the columella: peristome slightly thickened, reflexed; aperture subquadrate.

Alt. 22, diam. maj. 12 mm .
Aperture: alt. 9 , diam. $5 \cdot 5 \mathrm{~mm}$.
Ihub. (type specimen). Bitze, near the River Ja, Cameroons; several broken specimens also from Akok, 30-35 miles from the coast at Kribi.

Distinguished from $G$. liberiunc, Lea *, from Liberia, by its smaller size, thimer texture, and much finer transverse scuhpture ; moreover, the exceedingly fine punctate sculpture easily separates it from $G$. liberiana.

## Helicarion bitzeensis, sp. n. (Figs. 2, 3.)

Shell comeous, semitransparent, dark yellowish green; spire much depressed; whorls 3, here and there showing traces of slight malleation, puckered into irregular arcuate riblets or creases, on and between which appear fine lines of growth, the last whorl subcarinate, somewhat widely expanded towards the aperiure; sutures well impressed; aperture subovate, dilated above, rather laterally constricted.

Alt. 11, diam. maj. 25.5 mm .
Aperture: alt. 12, diam. 145 mm .
Hal. Bitze, near the River Ja, Cameroons (typ:) ; also a single specimen taken at Akok, 30-35 miles from the coast at Kribi.

## Helicarion umbrosolabiata, sp. n. (Figs. 4, 5.)

Shell corneous, thin, light olive-green, smmewhat inflated; whorls 3, marked with gowth-lines and occasionally creased into broad riblets, the last whorl scored with very fine irregular spiral scratches; sutures impressed; peristome folded inwards so as to form a narrow thickening, dark brownish green; aperture obliquely ovate.

Alt. 15 , diam. maj. 25.5 mm .
Aperture: alt. 13, diam. 14.5 mm .
Hab. Bitze, near the River Ja, Cameroons.

## Thapsia rosenbergi, sp. n. (Fig. 6.)

Shell depressed, perforate, discoidal, thin, polished, horny, light reddish brown; whorls $5 \frac{1}{4}$, sculptured with very fine, wavy, spiral strise and transverse lines of growth; base lighter

[^34]in colnur than the rest of the shell ; sutures impresse l, margined, whitish; umbilicus narrow, deep, partly concoaled by the reflexed columclla; peristome thin, acute; aperture oblique, broadly lunate.

Alt. $6 \cdot 5$, diam. maj. 13.5 mm .
Aperture: alt. 5 , diam. 5.5 mm .
11.b. Bitze, near the River Ja, Cameroons.

Type in British Museum.
A very variable species; one specimm is of a much darker colour than the others submittul $t$, me, and the margin of the suture, instead of being whitish, is of even a deeper shade of reddish brown than the rest of the shell ; another is somewhat lareer and flatter in propmtion than the type, but I am unable to separate them specifically.

## Achatina dacostana, sp. n. (Fig. 7.)

Shell ovate, pale hrownish frllow, painted with very indistinct greyi-h flame-mankings, especially moticoable on the fourth and fith whorls, and hearing trates of having $1, \ldots 1$ cosered with a very thin greeni-h-hown prostracum; whorls ti $\frac{1}{2}$, flattish, the upher finely gramar, the lat coarsely gramular above the periphery, smoth and shining belaw; sulures impresoch, crembate; aperture ovate; peristome achte; columellat descemdins obliguely and spravding intu a thin callus which jnins the upper margin of the peristome.

Alt. 75 , diam. maj. 37.5 mm .
Aperture : alt. 38 , dian. 22 mm .
Hab. East Africa.

## Achatina subcylindrica, sp. n. (Fig. 8.)

Shell thin, subcylindrical, pale greenish yellow; whonls $7 \frac{1}{2}$, regularly increaning, slightly convex, finely granular except on the lower half of the last whorl, winch is smouth; apex obtuse, somewhat flattened: sutures well impresseri, lightly crenulate; columella descenting in a curve; paistome thin, acute ; aperture inversely auriform.

Alt. $38 \cdot 5$, diam. maj. 13.5 mm .
Aperture: alt. 13 , diam. 7 mm .
Hab. Natal.
Allied to Achatina transeculensis, Smith*, hut difiering chiefly in its more cylindrical form. Hhtter whonls, and mather coarser sculpture.

* Journ. Conch. rol. i. pp. 351-352.

## Achatina variegata, Lk., var. gracilis, nov.

Shell less swollen and proportionately much narrow er than is the case with the typical $A$. variegater; the whorls are also rather more convex and the painting less regular.

Alt. (about) 120, diam. maj. (about) 58 mm.
Hab. West Africa.

## Callistoplepa tiara, sp. n. (Fig. 9.)

Shell oblong-ovate, thin, corneons, pale chestnut, ornamented on the upper whorls with zidzas transverse stroaks of purplish brown which becoms thickened and deepened in colour just above the sutures, so as to appear as a supersutural row of squarish dark purple blutches, and which are continued on the body-whorl as a peripheral interrupted band; the last two whorls are also painted with irregular creancoloured patches; whorls 6, sculptured with tine, wavy, spiab striæ crossed by irregular transverse ridges, giving to the shell a finely granular appearance; the sculpture, though continued towards the base of the shell, becomes obsolete below the periphery; sutures impressed, suberenulate; columella straight, dark purple; peristome simple, acute; aporture elongately inversely auriform.

Alt. 49, diam. maj. $2 \tilde{5}^{\circ} \cdot 25 \mathrm{~mm}$.
Aperture : alt. 30.75 , diam. 13.5 mm .
llab. Bitze, near the River Ja, Cameroons.

## Pseudachatina nodosa, sp. n. (Fig. 10.)

Shell ovate-conic, moderately thin, painted above with broad brownish-purple transverse flame-markings, between which the pale flesh-colvur of the shell is visible, coverel on the lower whorls with a thin, scaly, yellowish-brown periostracum ; whorls $7 \frac{1}{2}$, the first three granulated with fine spiral strix crossed by irregular transverse lines, the remainder irregularly coarsely nodulous, the last bearing two obsolete keels alont 9 mm . apart, the lower one situated at the periphery ; sutures crenulate, somewhat lightly impressed ; columella obliquely curvel, a thick callus, the outer margin of which is tinged with purple, joining it with the lip above ; peristome expanded, scarcely reflexed, livid purple; aperture obliquely inversely auriform ; interior of shell bluish white, a broad purple band appearing on the upper portion of the parietal wall.

Alt. 61, diam. maj. 29 mm .

Aperture: alt. 26 , diam. 13 mm .
Mub. (of type). Bitze, wear the River Ja, Camerom:a; specimens wrere also cullectel at Akok, $3^{\prime \prime}$ )-3.5 miles foom the coast at Kıibi.

In some rispects resembling ${ }^{\prime}$ '. matensi, d'Ailly * the present shell is, however, of a lighter texture, there is practically no basal zone of deoper coloration, and the proristome is always livil purple in colour, whereas MI. d'Aily makes a great pint of the constant whitenes of the peristome in his species.

> Pseuduchatina nodosi, Preston, var. eminens, nov. (Fig. 11.).

Inch uone elongate thon the trpical form, the kents on the last whorl are even more obsiflet, an! the whamella is less curved.

Alt. 89, diam. maj. 37.5 mm .
Aperture : alt. 33 , diam. 17 mm .
Hub. Bitze, near the River Ja, Cameroons.

## Pseudotrochus batesi, sp. n. (Fig. 12.)

thell chlong-turrite, thin, prate thest-coloured, tran-versely banded, spotted, amel tessellated with chestmut-hrown and cramy white, covered "ith a vely thin pale yellowish-brown priotracum; apex flatenerl; whorls $6 \frac{1}{2}$, the embryonic whorls submamillary and presentine under a lens a watherel an rarance, the later whons regularly furrowed with closely set, hood, very Hat, spiral ridges, and sculptared with very fine, wary, siral stria, crosset by irregular lines of glowh, somewhat angled above the puiphery; periphery strongly but hontly caninate; sutures impressed, lightly crenulate, narowly in argined, whitish; base of shell convexly elongate; columblia sloghtly excarated above, twisted at base, reddish brown and diffused into a callus, which joins the lip above and continues as a parictal calius throghout the interior of the shell; feristome angled, sharply acute ; aperture nearly quadrate.

Alt. $51 \cdot 5$, diam. maj. 30 mm .
Aperture: alt. 21.5 , diam. $13 \cdot 5 \mathrm{~mm}$.
Hab. Bitze, near the River Ja, Cameroons.
Type in British Museum.
A very renarkable shell, whose nearest ally apl ears to be

* Pihang till Kumgl. Srennka Vetenshaps-Alsudunem= Landineray; 22, Afd. 4, no. 2, 1896, pp. 9デ-98.
P. lechatelieri, Dautz.*, from Dahomey; from this it is distinguished by its more acute spire, submamillary apex, broader base, blunter peripheral carina, coloured columelia and parietal callus, flatly furrowed sculpture, and general colouring, which in $P$. lechatelieri is generally darker, especially on the base, while the chestnut bands on the spire are more pronounced, numerous, and generally confined to the lower portion of the whorls, which is not the case with $P$. batesi.

## Pseudotrochus efulenensis, sp. n. (Fig. 13.)

Shell oblong-turrite, flesh-coloured, irregularly painted with blotches and streaks of dark brownish purple and creamcolour, base of shell painted with a broad band of blackish purple just below the periphery, which gives place to a zone of creamy flesh-colour between it and the columella; whorls 7 , the embryonic whorls very flat, constricted and quite smooth, the later whorls gradually increasing, sculptured with fine, slightly wavy, spiral strix and transverse growth-lines, the last whorl carinate at the periphery; sutures lightly impressed, subcrenulate; columella greyish brown, descending somewhat obliquely and extending into a thin, minutely granular callus which reaches the lip above; peristome slightly expanded, brownish flesh-colour; aperture subquadrate.

Alt. 63, diam. maj. 29 mm .
Aperture : alt. 28, diam. 14.5 mm .
Hab. Near Efulen, S. Cameroons.
'Iype in British Museum.

## Pseudoglessula camerunensis, sp. n. (Fig. 14.)

Shell subulately fusiform, glossy, light brown, mottled and streaked with blotches and bands of a dark purple colour; apex slightly mammillate; whorls $8 \frac{1}{2}$, the first two and a half spirally striate and lightly, transversely costate, presenting a punctate appearance, the remainder sculptured with fine, closely set, transverse riblets, the last whorl bearing a thread-like carina at the periphery; sutures impressed; colnmella whitish, excavated above, curved below, somewhat obliquely truncate, a very light callus joining it with the lip above ; peristome simple, acute ; aperture inversely auriform.

Alt. 30.5 , diam. maj. 12 mm .
A perture: alt. 11, diam. 5 mm .

* Journ. de Conchyl. xl. 1892, p. 297 ; xli. 1893, p. 33, pl. i. Ann. d Mag. N. Hist. Ser. 8. Fol. iii. 13

Meth. (of type). Akok, 30-35 miles from the coast at Krihi, Cameroons; specimens also occurred at Bitze, near the River Ja.

Allied to P. chevata, Gray, from which it differs by its more cylindrical form and the very fine senlpture of the embrennic whorls, which in $P$. clacata are much more corarely costate; the last whorl and the aperture in the present species are also much longer.

Homorus foveolatus, sp. n. (Fig. 15.)
Shell narrowly subulate, dark bown, smoth, polishel, shanine ; apex mammillate; whorls $101!$, flattish, irreculanly marked with fine obligue crowth-lines, the last whon somewhat carmate at the periphory; sutures well impresel; columella lesem line in a curve, abowly truncte, extem ling into a calins which joins the lip abjove; peristome simple, acute ; aperture ovate.

Alt. $16 \cdot 25$, diam. maj. $3 \cdot 5 \mathrm{~mm}$.
Aperture: alt. 2, diam. 1 mm .
IIal, Akk, 30-3.5 miles from the coast at Kribi, ('amer,ons.

## Subulina jaensis, sp. n. (Fig. 16.)

Shell bluntly subuhate, thin, lichit yellowish flob-colour, summammillate at the apex ; whotls $4 \frac{1}{2}$. rather flat, the first two ant a half smonth except fir a mante infrasutural plicatim, the la-t six whorls chasely tramsmosely striate ; sutures soluermulate; columella curved and twisted; peristome acute; aperture elongately ovate.

Alt. $18 \cdot 75$, diam, maj. $4 \cdot 25 \mathrm{~mm}$.
Aperture: ait. $3 \cdot 75$, diam. 1.5 mm .
Hub. Bitze, near the River Ja, Cameroons.

## Fischeria messageri, sp. n. (Fig. 17.)

Slell thin, elongately uhlong, marked faintly with concentric lines of growth, covered with a smooth pale olivegreen promstracum; teeth small; posterior side very obtusely rustate; anturior side sumewhat acutely rounded; dorsil marins soping, especially anteriorly; ventral margin rom de l centrally, slightly excavated posteriorly.

Long. 15, lat. $25^{\circ} 5 \mathrm{~mm}$.
1iab. Senegal River.
Fischeria approximans, sp. n. (Fig. 18.)
Shell thin, elongately ovate, dark olive-green painted with
rays of a darker colour and covered with a smooth periostracum ; teeth small, the cardinal tooth on right valve bifid; posterior side obtusely rounded above, angled below; anterior side sharply rounded ; dorsal margins very gradually sloping ; ventral margin angled, somewhat produced centrally.

Long. 13, lat. 20.5 mm .
Hab. Podor, Senegal River.
Allied to $I$. leviguta, von Mts., but differing from that spectes by its angular and produced ventral margin, more sharply rounded anterior side, and more ohinse posterion side; moreover, the bifid cardinal tooth in the right value immediately distinguishes it from $F$. loevigata.

XXII.-Rhynchotal Notes.-XLVI. By W. L. Distant.

## Homoptera.

## Fam. Cercopidæ.

## Neotropical Genera and Species.

The Ncotropical Cercopidx are well represented in the British Muscum. In addition to those described by Walker it possesses the splendid Godman Collection from Central America worked out and described by Fowler. It has also during recent years acquired a large number of species from Ecuador and Bolivia, many of which are here described. The Fry Collection, bequeathed to the British Muscum by
the late Alexander Fry, also contained many South Brazilian species.

Dr. Jacobi has recently published the description of "Neue Cercopiden des Andengebietes," which comprise 41 new species and some new gencra, and I have again to thank that able homopterist for letting me see cotypes of all but five of these species.

## Subfam. Aphrophorines.

## Genus Avernus.

Avernus, Stisl, Hem. Afr. iv. p. (is (18466) ; id. Berl. ent. Zeitschr. x. p. 384 (1866).

Type, A. ocelliger, Walk.

## Avernus ocelliger.

Ptyelus ocelliger, Walk. List Hom. iii. p. 708 (1851).
Ptyelus interruptus, Walls. loc. cit. p. 715.
Avernus alboater, Stâl (part.), Berl. ent. Zeitschr. x. p. 384 (1866).
Hab. Colombia, Venezuela, Bolivia.
Stal had treated the Monecphora alboatra, Walk., as a synonym of the above. This is one of the few indubitable errors made by that great Rhynchotist, as alboatra differs in the shape of the head and the position of the ocelli from the generic characters given by himself for Avernus, which he founded for their reception. M. alboatra cannot therefore remain the type of the genus, which was described subsequent to his visit to the British Museum.
A. meridionalıs, Jac., is an allied species (var.?).

## Avernus balteatus, sp. n.

Ityelus eleninus, Bredd. MS.
Black; tegmina crossed near middle by a white fascia which narrows towards costal margin ; vertex much shorter than breadth between eyes, obtusely angularly rounded in front, on central anterior area reaching apex is a slightly depressed space with raised margins, which is couvex in front, truncate behind; pronotum centrally longitudinally carinate, its anterior margin somewhat strongly angularly rounded; scutellum discally angularly flattened, at base only centrally moderately foveate, both these areas centrally longitudinally incised; face without a central ridge; rostrum reaching the intermediate coxæ; posterior tibiæ with two strong spines; tegmina about two and a half times as long as broad.

Long., incl. tegm., 14 to 15 mm .
Hab. Ecuador; Balzapamba (Brit. Mus.).
The British Museum possesses two specimens of this species, purchased as one of "Breddin's co-types" some years ago, but I can find no trace of a corresponding description.

## Avernus affinis, sp. n.

Allied to $A$. balteatus, Dist., but the colour pale castaneous, not black, and the legs brownish ochraceous; the tegmina in addition to the white transverse fascia possesses three white spots on the apical third-the first, largest and rounded on costal margin, the other two more ovate and placed on disk in longitudinal series before apex ; head and pronotum a little narrower than in $A$. balteatus, the latter also finely granulose.

Long., incl. tegm., 14 mm .
Hab. Brazil (Fry. Coll., Brit. Mus.).

## Neoavernus, gen. nov.

Vertex about as long as breadth between eyes, somewhat broadly rounded in front ; ocelli at base, close to eyes, very much nearer to eyes than to each other, the lateral and apical margins a little upwardly ridged; face without a central carination; clypeus foveately depressed on each side at base; rostrum slightly passing the intermediate coxæ; pronotum with a central longitudinal carination which is more prominent and distinct on disk, the anterior lateral margins oblique, shorter than the posterior lateral margins, which are slightly sinuate ; anterior margin roundly truncate, posterior margin strongly subangularly concave in front of scutellum, which is longer than broad; posterior tibir with two strong spines; tegmina twice as long as broad.

Type, N. alboater, Walk.
Differs from Avernus by the larger and more rounded vertex, different position of the ocelli, and short tegmina.

## Neoavernus alboater.

Monecphora alboatra, Walk. List Hom. iii. p. 682 (1851).
Avernus albouter, Stål (part.), Berl. ent. Zeitschr. x. p. 384 (1866).
Hab. Colombia (Brit. Mus.).

## Genus Sphodroscarta.

Sphodroscarta, Stål, Hem. Fabr. ii. p. 17 (1869).
Type, S. gigas, Fabr.

## Sphodroscarta bimaculata, sp. n.

Black; eres and abdominal segmental mareins ocluraceoms; tegmina with two large white spots on immer margin, ome crossing clavis a little before its apex, the other and smatler at the lower part of apical margin; wings dark fuliginous; vertex a little more than half an lomg an breadth between eyes, somewhat angularly produced, the lateral margins oblique, the basal margin whtusely angularly sinuate, two short carmate lines mot rachmer hase, cach situate ontside the region of the ocelli ; promotum not carinate, but centrally longitudinally depresed, the atherone lateqal margins very short, the posterior lateral margins abont as long as the posterior margin, which is strongly anizularly (oncate; scutellum much longer than hrod. its dish centally longitudinally depressed ; posterion tibie with two strong spiucs.

Long., excl. tegm., if 12 mm .; exp. tegm. 30 mm .
Hab. Bolivia; Yungas de la Paz.

## Subfam. Cercopinet.

## Genus Hyboscarta.

Type, H. rubrica, Jacobi.
Hyboscarta insignis.
Monecphora insignis, Walk, List Hom., Suppl. p. 178 (18.58).
Hab. Amazons.
Hyhoscarta semivitrea.
Sphenorhina semivitrea, Walls. List It m... suppl. p. i-t (12.iか).
Hab. Amazons.

## Hyboscarta tricolor, sp. n.

Head, pronotum, scutelhum, body beweath, anterior and intermediate femora (posterior legs mutilated in specimen described), and less than basal half of tegtuma, sang̣ineous; tro central spots to mesosternum, anterior and intermediate tibise and tarsi, black; a little more than apical half of tegmina ochraceous, subhyaline, the lateral and subapical margins of this area broadly black, extending to apex of clavus; pronotum and tegmina thickly finely punctate;
face moderately compressed, laterally strongly trausversely striate, centrally longitudinally ridged.

Long. $8 \frac{1}{2} \mathrm{~mm}$.
Hab. Brazil ; Lages.

## Genus Ischnorhina.

Ischnorhina, Stal, Hem. Fabr. ii. p. 14 (1869).
Sulgen. Schistogonia, Stål, loc. cit.
Types, I. sanguinea, Fabr., and I. ephippium, Fabr.

## Ischnorhina valida, sp. n.

Head above and beneath (including face), pronotum, scutellum, and sternum sanguineous; abdomen above and beneath and the legs black; base of abdomen narrowly sanguineous; tegmina sanguineous, with a broad black fascria commencing at about one-fourth from base and extending and occupying rather more than the costal area, the apical area, and continned along the inner margin to about onefourth from base, the sanguincous coloration thus being confined to the basal area and a medial longitudinal fascia not extending beyond apical area, the extreme costal margin for about one-fourth from base dull obscure ochraceous ; wings pale shining fuliginous with the reins piceons; rertex with the central lobe narrowed and anteriorly produced; face sharply compressed, as in typical forms of "'phenorhime, and prominently transversely striate on each side; pronotum prominently foveately depressed on each side of anterior area, the anterior lateral margins moderately ampliate and reflexed; scutellum quadrangularly ridged, apex also ridged.

Long., excl. tegm., $9 \frac{1}{2} \mathrm{~mm}$.; exp. tegm. 30 mm .
Hab. Cayenne (Brit. Mus.).
Allied to I. imrulida, Jacobi (a species I have not scen), from which it differs by the colour of the stemum and structural characters detailed above, which are not given by its describer in his diagnosis.

## Ischnorlina juno, sp. n.

Vertex, pronotum, scutellum, face, lateral areas of prosternum, and base of abdomen sanguineous; disk of scutellum, abdomen, body beneath, and legs black; tegmiua black, base of costal area and base of posterior claval area (both these markings united at base) sanguineous; wings fuliginous, the veins piceous, extreme base sauguineons; vertex about as long as breadth betweeu eyes, the apex angularly projecting, a longitudiuat impressed line in front
of each ocellus; pronotum foveately impressed on each side of anterior area, the lateral margins moderately sharply reflexed; face strongly compressed, posteriorly pointed, thence obliquely straight to clypeus, centrally longitudinally ridged; posterior tibise with a strong spine a little before apex; tegmina three times as long as broad.

Long., excl. tegm., 9 mm . ; exp. tegm. 30 mm .
Hab. Peru (Coll. Dist.).

## Ischnorhina grandis.

Sphenorhina grandis, Dist. Tr. Ent. Soe. Loml. 18.8, p. 179; Waterh. Aid Identif. Ins. ii. pl. 148. fig. 5 (1884).
Tomaspis layuers, Bredd. Soc. entomol. xix. p. 58 (1904).
Sphenorhina laqueus, Bredd. Cotype purchaved by Brit. Mus.
Hab. Colombia; Ecuador.

## Ischnorhina bogotana.

Sphemorhina longotena, Di-t. Trans. Ent. Soc. Lond. 185, p. 179 ; Waterh. Aid Identif. Ins. ii. pl. 152. fig. 2 (1884).
Hub. Bogota.

## Ischnorhina flammans.

Sphenorhina flammams, Walk. List INom.. Suppl. p. 170 (] [85) ,
sphemerhina ucuta, Sial, liio Jan. Hem. ii. 1. 14 (1-5) ; id. (i)sv. Vet.-Ak. Förh. 1862, p. 493.
Hab. Brazil.

## Ischnorhina rufivaria.

Sphenorhina ruficaria, Wall. List Ium. iii. p. 686 (1s.51).
Hab. Brazil.
Ischnorhina xanthomela.
Sphenorhina a anthomela, Walk. List Hom., Suppl. p. 180 (185, $)_{\text {) }}$.
Hab. Amazons.
Genus Tomaspis.
Tomaspis, Amy. \& Serv. Hist. Hém. p. 560 (1843). Tpe, T. furcata, Germ.
Monecphora, Amy. \& Serv. loc. cit. p. 562. Type, M. cmyulatu, Le P. \& Serv.
Sphenorhina, Amy. \& Serv. loc. cit. Type, S. linerslatus, Amy. \& Serv.
I have previously reqarded the above divisions of Amyot and Serville as generically distinct and have acted accordingly, for if we compare the types (as above) there is every reason to do so. Not only is there then found a distinct structural
difference in the face, but in the type of Tomaspis there is a fundamental difference in the length and structure of the tegmina. But when a large series of the species that should be arranged under these three proposed genera is examined, the differences in too many cases become evanescent and relative. Stål, who originally used them as distinct genera (Rio Jan. Hem. 1858), subsequently (Hem. Africana, 1866) treated them, with the addition of Triecphora, Amy. \& Serv., as synonyms of Tomaspis, and in this generic conclusion he has been followed by Fowler and Jacobi. From this decision I ouly differ by not including Triecphora, a Palearctic and Ethiopian genus also treated as distinct by Puton, Melichar, and other writers. From Berg (Hem. Argent., 1879) I dissent by including Sphenorhina, and agree with him in excluding Triecphora.

It is not, however, to be regarded as improbable that this large and miscellaneous genus, Tomaspis, as thus understood will yet be consistently divided. The differential characters given by Amyot and Serville for their three proposed genera are largely and principally confined to facial structure, and these have proved a hindrance rather than a help, by monupolising the attentions of homopterists to the neglect of other characters, many of which undoubtedly exist and will probably be used by some future analytical student.

## Tomaspis parana, sp. n.

Head and pronotum sanguineous; basal half of head, two spots on anterior area of pronotum-connected with the anterior margin,-scutellum, abdomen above, and body beneath black; legs black or picecus; face, apex of scutellum, and lateral margins of prosternum sanguineous; tegmina sanguineous, a costal streak extending from base to apex (near base and beyond middle not reaching the costal margin), apical margin, a ceutral longitudinal fascia, commencing near middle and extending to apex, and a claval streak black; wings fuliginous; face sanguineous, strongly, centrally, longitudinally ridged, moderately compressed, not terminating in an obtuse point; rostrum reaching the intermediate coxæ; tegmina narrow, more than three times as long as broad.

Var. a.-Legs dull testaceous red, apices of the femora piceous.

Long., excl. tegm., ठ 12 , ¢ 17 mm . ; exp. tegm. ठ 39 , of 44 mm .
Hab. Brazil ; Parana (E. Dukinfield Jones, Brit. Mus.).

Tomaspis consanguinea, sp. 11.
Allied to $T$. purumu, Dist., lut the tegmina comparatively shorter and broader, not quite three times longer than broad: hoad and pronotum smgumeous, without hack markings; scutellum and legs wholly sanguineons; tecemma similarly fasciated as in T. paranu.

Long., excl. tegm., of 16 mm . ; exp. term. 45 mm .
Hab. Rio Grande do Sul (Brit. Mus.).

## Tomaspis chapada, sp. n.

Sarguineous; lateral lobes and base of lead, two laree spots on anterior area of the pronotum and ermeected with the anterior margin, sentellom, abdomen above, bols bencath, and legs black; face and lateral margins of ponstemum sangrineous; tegmina sanguncons, costal and apical marems the former broad and ocrupging the costal anca for abont two-thirds its length and the latere continued to apex of clavus), a broad echtral somewhat short longiturlinal streak between middle and apical area, and a streak at middle of upper claval margin black: wings fulogoous ; teymina barely three times as longe as broad; face moderatels compresed, strongly econtrally ridged, terminating in an obsolete pomt outwardly and then subtruncately directed to elypens: rustrum reaching the intermediate coxæ.

Far.--Teqmina narrowly margined with black as in typical form, but not broadened at costal area, the isterior biack streaks practically obsolete.

Long., excl. tegm., 12 mm . ; exp. tegm. $30-35 \mathrm{~mm}$.
Hub. Contral Brazil; Chapada (A. Robert, Brit. Mus.,.

## Tomaspis brasiliensis, sp. n.

Body and legs black; apex of head, lateral margins and a central longitudinal fascia to pronotim, and extreme base of abdomen above sanguineous; teymina sanguineous, costal and apical margins the first much broadened at costal are at and thus continued for about thrce-fourths from base, the latter continued to apex of clarus) and a broad median longitudinal fascia which occupies nearly upper half of clavus, is continued to ncar apex, and is fractured near claval margin, black: wings fuliginous; face black, in structure resembling that of the previously described species T. chafuda; rostrum almost reaching the posterior cose ; tegmina not more than three times as long as broad.

Long., excl. tegm., 13 mm. ; exp. tegm. 40 mm.
Hab. Brazil (Fry Coll., Brit. Mus.).

## Tomaspis spectabilis, sp. n.

Heari, mronotum, and scutellum dull reddish castancons; abdomen above, face, sternum, and legs sanguineous; abde)men leneath, spots and suffusions to sternmm, longitudinal stripes to intermediate femora, posterior femora (excludines apices), tarsi (excluding extreme base), and apical joint of rostrum black; abdomen beneath with the posterior sesmental margins (narrowly) and the lateral margins (somewhat broadly) sanguineous; tegmina ochraceros, narrow costal margin extending round apex to apex of clavis, centre of posterior claval margin, claval apex, and an irregulat contral longitudinal fascia, irregularly widened at about onethird from base and continued to near apex, black; claval suture piceous; wings dark fuliginous, their extreme bases sanguineous; vertex subangulate in 1rout and distinctly longitudinally carinate; face moderately compressed, strongly centially carinate and transversely striate (of the lionechluite form) ; pronotum very fincly and thickly wrinkled, obscurely finely, centrally, longitudinally carinate, the carination mot reaching the anterior margin, the anterior lateral margins slightly reflexed; rostrim reaching the intermediate coxie.

Long., excl. tegm., 10 mm . ; exp. tegm. 29 mm.
Hab. Bolivia (J. Steinbach, Brit. Mus.).

## Tomaspis fryi, sp. n.

Tertex pieenus, with a slightly arched transverse ochracenus fascia between the eves; pronotum with the baval two-thinds piceous-hown, margined anteriorly with a transterve black line, in front of which the anterior area is ochraceous, as is also a lateral spot on each side behind the black line; scutellum piceous, with a pale ocliraceous spot at commencement of apical area; abdomen abore piceons, sanguincons at base, the comexirum ochraceous with hack spe,ts: face orange-rellow with a black basal line; body beneath and legs paie ochraceous; sternal aud coxal spots, apices of femora, anterior tibix, hases and apices of intermentate and posterior tibir, the tarsi, narrow segmental margins and a longitudinal line at inner margins of connexivum, piccous or black; tegmina black; basal half of clarns, a basal lincur costal spot, a longitudinal streak to corium, commencing at base above clavus and gradually narrowing to a subapical and subcostal quadrate spot, pale ochraceous; wings fuiiginous; face broad and flatly rounded, of the Dionecplioria form ; vertex about as long as breadth between eyes, sub)conically rounded in front; scutellum broan! discally
foveate (imperfectly seen in the badly pimned type); tegmina about three times as long as broad.

Long., excl. tegm., $8 \frac{1}{2} \mathrm{~mm}$. ; exp. tegm. 24 mm .
Hab. Brazil (Fry Coll., Brit. Mus.).
Tomaspis jonesi, sp. n.
uniformis, Sign. MS.
Head, pronotum, and scutellum pale ochraceous; ablomen above, body beneath, and legs sanguincous; a spot near apex of scutellum, anterior and intermediate tarsi and apices of posterior tarsi, eyes, and apex of rostrum black; lateral margius of prosternum ochraceons; tegmina pale ochraceous, with a broad transserse fascia near middle and about the apical fourth black; wings pale smoky hyaline; vertex about as long as breadth between eyes; face broad, rounded, not angulate (of the Monecphora type), centrally longitudinally ridged; rostrum reaching the intermediate coxæ ; pronotum very finely transversely wrinkled; scutelium discally foveately depressed ; posterior tibiee with two spines, one near base, the other a little beyond middle.

Long., excl. tegm., 8 mm . ; exp. tegm. 24 mm .
Hab. Brazıl ; Parana (E. Dukinfield Jones, Brit. Mus.) ; Rio Negro (Coll. Dist.).

Many years ago I received a specimen labelled uniformis, MS., from my lamented friend Dr. Signoret, and probably there is a similarly identified specimen in the Vienna Muscum, in which Dr. Signoret's collection is located.

## Tomaspis saccharina, sp. n.

Tomaspis pictipermis, Ǔhler (nec Stâl), Proc. Zool. Suc. Loud, 1s9\%, p. 58.

Head, pronotum, and scutellum dark bronzy; abdomen above and beneath sanguineous; face, sternum, legs, and a sublateral fascia on each side of abdomen beneath bluish black; tegmina piceous brown, with two transverse whitish fasciæ, the first broadest and slightly oblique before middle, the second narrower and nearly straight beyond middle; wings hyaline with the veins fuscous; vertex broader than long, rounded in tront, centrally carinate and longitudinally depressed on each side before the eyes; face compressed, centrally lougitudinally carinate, somemhat regularly rounded to clypeus (Monecphora type); tegmina less than three times longer than broad.

Var. a.-A broad whitish streak in claval suture, united with the first transverse whitish fascia.

Var. h.-Basal third of tegmina almost totally whitish, only divided by the claval suture, which is piceous brown.

Hal. Trinidad (Brit. Mus.) ; Antilles; St. Vincent and Grenada (Smith, Brit. Mus.).

Reported from Trinidad as a destructive pest to the cultivation of sugar-cane.

As pointed out by Fowler, the T. pictipennis, Stål, is a synonym of the 11 . postica, Walk. Apart from the considerable differences in colour and pattern, T. postica has a less developed and more evenly rounded face than T. saccharina.

## Tomaspis dominicana, sp. n.

Head, pronotum, scutellum, and abdomen above black, lateral margins and apex of scutellum and base of abdomen sanguineous; body beneath and legs black; coxal spots, sternal spots, and broad lateral margins to meso- and metasterna sanguineous; tegmina black, with five sanguineous spots, situate one near base of clarus, one above apical end of clarus, two on medial vein (one at about one-third from base, the other on apical area), and the fifth costal berond middle; wings fuliginous; rertex almost as long as breadth between eyes, medially longitudinally carinate, between this cariuation and the eyes a foveate depression on each side; scutellum strongly discally foreately depressed, the margins of this foveation raised, united posteriorly and continued to apex ; face rounded to clypeus (Monecphora type) ; posterior tibia with two strong spines, the shorter near base, the longer near middle.

Long., excl. tegm., 8 mm .; exp. tegm. 19 mm .
Hab. Nominica (Brit. Mus.).
Received from the Imp. Dept. Agric., West Indies.

## Tomaspis jamaicensis, sp. n.

Head, pronotum, and scutellum black; apical area of vertex and about basal half of pronotum (not reaching the anterior lateral margins) bright ochraceous; abdomen above and beneath and legs sanguineous; head beneath and sternum black, the latter spotted and suffused with sanguineous; face bright ochraceous; tegmina pitchy black, with two Jarge bright ochraceous spots, the first and largest extending through clavus and reaching the subcostal vein at about one-third from base, the second spot smaller, central, and subapical; wings pale fuliginous; face rounded to clypeus (Monecphora trpe) ; vertex scarcely as broad as breadth
between eyes, not carinate; tegmina about two and a half times as long as broad ; posterior tibiae with two strong spines, the first and shortest mar base, the second and longer near middle.

Long., exel. tegm., 9 mm. ; exp. tegm. 26 mm .
Hub. Jamaica (Brit. Mus.).

## Tomaspis multicolor, sp. n.

Hear, pronotum, and sent-llum black, erevishly pilose; a spot on cach lateral marsin of vertes herwen apex and eyes and continued beneath between base of face and eyes, and lateral marcias of pronotum ochraceons; basal marcin of pronotum and lateral maruns and apex of scotellum purplish reel ; body beneath black; lateral margins of prostomm, cosa, lears, and apex of abdomen sangumernis; apieces of tarsi black; teremina stramineshs; musins and apes of clasus, basal fouth of corium, a central transweres fascia broadest on costal margin and extending to apex of rlavos, and apical fourth bhack; reptex mueh shopter than breath between eyes, broddy romeded in front, distinctly contrally lomeitudinally cominate; fare of the Monecplosia type, somewhat browi, flattoned at sides, centrally lonsitmbinally carmate and transversely striate, gradually convexly contimel to clypens; pasterior tibite with two prominent spines, one near base, the longer nearer apex.

Long., incl. team., 11 mm .
Muh. Central Brazil; Chapada (A. Robert, Brit. Mus.).
This species may be placed near M. scita, Walk.

## Tomaspis dissimilis, sp. n.

Vertex dull testaceous red, eves greerish with their posterion margins hack; pronotum stramineous, a dull testaceousred patch behond middle of anterior margin, followed by aut mute. 1 with a transerse black spot ; scentellum pienous, its laterai mawins stramineons; body beneath and lews dull ochraceons: face, disk of prosternum, anterior aud intermediate femora, and abdomen above dull testaceous red ; apex of rostrum, extreme apices of femora, anterior tibise and tarsi, bases and apices of intermediate tibise, the intermeliate tarsi and apices of posterior tarsi, black; termina dark lutenus, a short basal streak on costal area and an o! lique basal fascia occupying nearly half of clavus stramineons: wings subhyaline, the abdominal area piceous; vertex about as long as broad between eyes, the anterior margin broadly romded, a longitudinal impression on each
side a little before the eyes; face somewhat broarl, only moderatelv compressed, rombly and evenly continued to (lypus (Momecphora type); rostrum reaching the intermediate eoxe ; pronotum densely and very finely wrinkled, a distinet broad depression at the middle of the black spot; posterior tibir with a long spine near middle and a short spine near base.

Long., excl. tegm., 8 mm . ; exp. tegm. 23 mm.
Hab. Colombia; R. Dagua (Brit. Mus.).

## Tomaspis astralis, sp. n.

Ifead, pronotum, and scutellum bright shining olivaceous green, shortly palely pilose; ablomen above, body beneath, and leys testaccons red: heal bencath, anterior and intermediate tibise, apiess of posterior tibie, the tarsi, aud aual segment black; tegmina black, two short basal testaceousred streaks, one on posterior claval margin, the other above clavis, six ochraccous spots, situate one and smallest near middle of clavas, two in almost transverse series about onethird from base, and three at commencement of apical area (one on costal margin, one on inner margin, and the thurd ou disk a little berond the others) ; wings pale fuliginous ; vertex about as long as breadth between eyes, somewhat angularly rounded anteriorly, strongly centrally longitudinally earinate, depressed on each lateral area, where there is a short longitudinal incised line; pronotum with a transverse cicatrice on anterior margin, from which proceeds a short central lomgitudinal carination not reaching middle; fice a little angulate (intermediate between the Monecphora and Syhenortina types) ; posterior tibie with two spines, a very short one near base, and a much longer one near apex.

Long., excl. tegm, 5 mm . ; exp. tegm. 16 mm .
. Hab. Bolivia; Yungas de la Paz (Brit. Mus.).

## Tomaspis funebris, sp. n.

Vertex, pronotum, and scutellum black; lateral margins of vortex in front of eyes narrowly testaceous ; abdomen above dull samguineons, the central area and comexivom somewhat piscons; body bencath and legs black, basal magin of face testaceous; tegmina black; wings fuliginous, samguincous at base; vertex about as long as breadth botween eyes, somewhat anzularly romded in front; centrally longitudinally carinate, transversely impressed near middile and in front of this impression, the margius of the rentral area or lobe are also ridged; pronotum rugulosely
punctate, the anterior lateral margins distinctly reflexed; scutellum transversely striate, moderately foveately depressed on disk; face moderately compressed, slightly angulate near middle (between the Monecphora and sphemorhina types), strongly centrally ridged, transversely coarsely striate on lateral areas; rostrum reaching the intermediate coxa; posterior tibie with a strong spme beyond middle and a very short spine near base ; tegmina about two and a third times as long as broad.

Long., excl. tegm., f 15 mm .; exp. tegm. 38 mm .
Hab. Peru; Chandraunayo (Brit. Mus.).

## Tomaspis noctua, sp. n .

Vertex, pronotum, and scutellum black; frontal margins of anterior lobe, ocelli, eyes, and anterior lateral margins of pronotum pale ochraceous; lateral margins and apex of scutellum and abdomen above reddish testaccous; body beneath and legs black; a spot on each side of bise and the central ridge to face and the lateral margins of abdomen pale ochraceous; base of rostrum, apices of anterior femora beneath, obscure longitudinal streaks to femora beneath, apices of tarsi (excluding claws), and narrow posterior abdominal segmental margins reddish testaceous; tegmina black, basal third of costal margin (widened at its apex), discoidal vein for about one-third from base (where it branches, the two branches united at their ends), upper claval margin and claval vein for about two-thirds from their base, and a subcostal spot before apical area sanguineous; wings fuliginous, the reins black, the base sauguineous; face compressed, centrally ridged, scarcely pointed and moderately continuous to clypeus (intermediate between the Monecphora and Sphenorhina types) ; rostrum reaching the intermediate coxa; vertex centrally ridged, somewhat angulate in front, lougitudinally incised between the ocelli and eyes; pronotum rugulose and punctate, with an obscure central longitudinal caninate line which is only distinct on disk, the anterior lateral margins reflexed; scutellum longer than broad, transversely striate; tegmina about two and a half times as long as broad.

Long., excl. tegm., 여 $14 \frac{1}{2} \mathrm{~mm}$. ; exp. tegm. 40 mm .
Hab. Amazons; Nanta (Degand, Brit. Mus.).

## Tomaspis combusta, sp. n.

Vertex black, anterior half in front of eyes reddish yellow; ocelli bright yellow; pronotum black, the lateral margins
broadly reduish yellow; abdomen above and beneath reddish yellow; sternum and legs black; face, lateral margins of prosternum, anterior and intermediate fenora (excluding base and apex), apices of posterior femora, and tarsal claws reddish yellow; tegmina black, hasal third, costal margin (abruptly widening at about one-third from apex, continued round apex and terminating on posterior margin at apex of clavus) reddish yellow; wings pale fuliginous, extreme base black; vertex about as long as lireadth between eyes, centrally longitudinally tricarinate in front of eyes, centrally carinate between the ocelli, and with an impressed line on each side of the ocelli ; face strongly centrally longitudinally ridged, moderately angulated posteriorly (intermediate between the typical forms of Monecphorer and Sphenorhina); rostrum reaching the intermediate tibir; pronotum punctate and slightly rugulose, centrally longitudinally carinate, the carination not reaching base, the lateral margins strongly reflexed ; tegmina not three times longer than broad, densely finely punctate, the apical area strongly reticulately veined.

Long., excl. tegm., 11-11 $\frac{1}{2} \mathrm{~mm}$. ; exp. tegm. 32 mm .
Hab. Bolivia (Steinbach, Brit. Mus.).
'Lo be placed near T'. cercopoides, Walk. So far as I understand Breddin's descriptions, the T. erigena and T. rodupepla of that writer should also belong to this group.

## Tomaspis chilensis, sp. n.

Tertex, pronotum, and scutcllum piceous; broad anterior margin to vertex, broad lateral margins (which inwardly are vaguely defined and tend to produce discal suffusions) and a narrow anterior margin to pronotum ochraceons ; aldomen (abore and beneath) and face ochraccou.: stemum and legs piceous, the femora more or less streaked with ochraceous; tegmina piceous, the basal area indefinitely ochraceous, more strongly outwardly accentuated by a transverse spot on costal area; wings pale fuliginous ; rertex almost as long as breadth between eyes, centrally longitudinally carinate, and on each side of the contral carination is a short curved carinatiou from a little in front of ocelli to apex ; pronotum feebly centrally carinate, obsoletely so ou posterior half, the lateral margins distinctly reflexed; face compressed, centrally longitudinally strongly carinate, a little angulate posteriorly (intermediate between the Monecphora and siphenorhina types), very strongly laterally tramsversely striate; posterior tibiae with two strong spines, the shorter almost at base, the ionger at about one-third from apes; termina about two and a half times as long as broad.

Ann. de Mag. N. Hist. Ser. 8. Vol. iii,

Long., exel. tegm., 11 mm .; exp. tegm. 32 mm .
Hab. Chili.
The type of this spocies was given me many years ago by my late friend Stephen Barton, a coleopterist. He had received it from Edwin Reed, by whom it had been collected.

## Tomaspis fraseri, sp. n .

Head, pronotum, scutellum, and sternum castancous; legs and abdomen testaceous red, the latter paler above than bencath; tegmina pitchy black, sullu-ed with sanguineous on basal area, followed by two spots in oblique series (one in and the other above clavis), a subcostal spot before apical area, and another more oblique spot parallel to it near inner margin sanguincons; wings pale fuliginons; vertex about as long as breadth between cyes, rather angnlarly rounded in front and centrally longitudinally carinate; pronotum wrinkled and thickly finely punctate, centrally lomgitudinally carinate; scutellum foreately depressed on disk, the apical area transieredy wrinkled; face compressed, angulate posteriorly, strong! centrally longitudinally carinate (Syphorkina type) ; posterior tibie with two spines, the shorter near hase, the longer near apex ; tegmina about two and a half times as long as broad.

Long., excl. tegm., 10 mm . ; exp. tegm. 23 mm .
Hub. Ecuador; Cuença (Fi.aser, Brit. Mus.).

## Tomaspis proserpina, sp. n.

Tertex, pronotum, scutcllum, face, sternum, and legs sanguincous; abdomen and spots to mesonotum black; base of abdomen abore sanguincous; posterior femora (more or less) and apices of posterior tibite and tarsi piceous ; tegmina black, basal fourth and costal margin sanguineous, the basal red space usually but not invariably marked with a macular piceous stripe; vertex about as long as breadth betwecu eyes, a little pointed anteriorly, foveately depressed at apes and on each side before the eyes; face moderately compressed, pointed posteriorly (Sphenorhina type); pronotum finely granulose, centrally ridged from anterior margin to about middle, on anterior area and on each side of the ridge distinctly foveately depressed, lateral margins oblique, sharply and distinctly reflexed; scutellum with the disk ovately foveate; posterior tibie with a strong spine near apex and a short spine near base; tegmina about two and a half times as long as broad.

Long., excl. tegm., 7 mm . ; exp. tegm. 20 mm .
Hab. Bolivia; Yungas de la Paz (Brit. Mus.).

Tomaspis heles, sp. n.
Tertex, pronotum, scutellum, base of abdomen, face, clypeus, and broad lateral areas to the prosternum ochraceous; abdomen above, body beneath, and legs shining black; tegmina black, the basal fifth golden yellow; wings pile fuligmous; vertex about as long as breadth between eyes, a little angularly narrowed before eyes, longitadinally impressed on each side of ocelli ; face compressed, posteriorly pointed, thence oblique to clypeus, centrally longitudinally ridged; pronotum foveately depressed on each side of anterior area, the lateral margins sharply reflexed ; posterior tibire with a prominent spine a little before apex; tegmina about two and a half times as long as broad.

Var.-Tegmina with a golden-ycllow costal spot a little beyond middle.

Long., excl. tegm., $8 \frac{1}{2}-9 \mathrm{~mm}$. ; exp. tegm. 23-24 mm.
Hab. Bolivia; Yungas de la Paz (Brit. Mus.).
Allied to T. proserpina by the somewhat angulate vertex, which but for intermediate forms would apparently denote another genus.

## Tomaspis dimorpha, sp. n.

J. Vertex, pronotum, and scutcllum catancous-brown; abdomen above black, its base sanguincous; body beneath black, legs piceous; sternum and coxic more or less testaceons red; tegmina brownish ochraccons, the apical area yellowish, defined inwardly by a transverse black fascia which is continned on costal margin to apex, the pale apical area very coarsely reticulately veined, and in most of these cellules is a piccous-brown spot; wings pale ochraccous, slightly sanguineous at base.

Var.- \& . Vertex, pronotum, scutellum, and tegmina black, on the latter the transverse fascia defining the pale apical area is thus indistinguishable.

Face compressed, elongate, almost perpendicularly directed downward, where it terminates in a somewhat sharp point (Sphenorlina type), and strongly centrally longitudinally ridged ; vertex about as long as breadth between eyes, with a central longitudinal carination, on each side of which is another and shorter carination not reaching base; pronotum rugulose and punctate, centrally longitudinally carinate, broadly foveately depressed on each side of anterior area, the anterior lateral margins distinctly reflexed ; scutcllum with the disk broadly foreately depressed; teginina about two and one-third times as long as broad.

Long．，excl．tegm．，of \＆ $8-9 \mathrm{~mm}$. ；exp．tegm． 22 mms ．
Hab．Bolivia；Yungas de la Paz．
I possess a single specimen of each sex of this species， which vary as above．Whether this represents sexual di－ morphism，as I am inclined to believe，or simple variation， can only be decided when a series of specimens are available for examination．

## Tomaspis distinguenda．

sphemorhinas distinguenda，Walk．Li－t Ifom．，Suppl．p．Ine（1sis）．
 ii．p．183，tab．xi．figs． 10 \＆ 16 （1897）：excl．syn．
Walier＇s type was from Venczucla；all the specimens collected by Champion were from Panama．

## Tomaspis nigricans．

Tomaspis nigricans，Àmy．\＆Serv．IIist．Hém．p． 560 （1843）．

The（ercopis marginatn，Fab）r．，has heen shown by Stal to be a Gypona（Hem．Fabr．ii．p．85，1869）．

## Tomaspis festa．

Cercopis festa，Germ．Mag．Ent．iv．p． 40 （1821）．
Sphenorhina fes／a，Still，lio Jan．Hem．ii．p． 14 （1858）．
Sphenorfina parallela，Walk．List Hom．iii．p． 694 （ 3851 ）．
Tomasspis liemata，Fowl．（part．），Bisul．Centr．－Am．，Rhynch．Horr．ii． p． 189 （1897）．
Fowler has included the S．purallelu，Walk．，as a synonym of $S$ ．linentu，Walk．The two species are，hoverer，quite distinct by markings of tegmina and shape of face，and Stal correctly pointed out the identity of the former species with C．festa，Germ．

## Tomaspis stellata．

Sphenorhina stellata，Walk．List Hom．iii．p． 691 （1851）．

Tomaspis semifascia．
Monecphora semifascia，Walk．List Hom．iii．p． 679 （1851）．
Monecphora demissn，Walk．loc．cit．p． 684.

## Tomaspis flexuosa．

Monecphora flexuosa，Walk．List Hom．iii．p． 677 （1851）．
Monecphora viridescens，TValk．loc．cit．p． 679.
Monecphora vacillans，Walk．Ins．Saund．，Iom．p．\＆fi（lsよショ）．

## Tomaspis costaricensis.

Sphenorkina costaricensis, Dist. Ent。 Month. Mag. xvi. p. 61 18i9). Tomaspia quatuenrdecim-notate, Fewl. Biol. Centr,-Am., Rhynch. Hom. ii. p. 177, t. xi. fig. 5 (1897).

## Tomaspis incompleta.

Monecphora incompleta, Walk. List Hom. iii. p. $68 \pm$ (1851).
Sphenorhina diluta, Walk. Ins. Saund., Hom. p. 92 (1858).
Although Walker descrites the colour of incompleta as "pale brown, skining" and that of dilutu as "blackish green," the colours of the two forms are practically identical, and "brown" must be substitated for "blackish green."

## Tomaspis compressa.

Cercopis compresen, St. Farg. \& Serv. Enc, Méth, x. p. 6ifis, 13 (1:25).
Var. a (typical).-Pronotum sangrineous; legs black, posterior femora and bases of posterior tihite sanguineous. Cayenne (Brit. Mus.). Original habitat of describers.

Var. b.-All the femora sanguineous or ochraceous, tibia and tarsi black; apical margin of tegmina black, but with the apical area sometimes suffused with black. Amazons (Brit. Mus.) ; Ega (Coll. Dist.).

Var. c (Stoll, Cic. fig. 112).-Pronotum and legs black. Surinam, fide Stoll. This tisure is said to represent a form of the species (St. Farg. \& Serv.).

## Neosphenorhina, gen. nov.

Vertex about as long as breadth between eyes, angularly narrowed anteriorly, centrally longitudinally carinate, and longitudinally ridged near the anterior margin of each eye; face very strongly compressed, almost straightly deflented downward to a point opposite base of clypeus, to which it is then truncately directed; rostrum slightly passing the intermediate cose; pronotum a little longer than broad, the anterior lateral margins oblique, not convexly rounded but a little concavely sinuate, longer than the posterior lateral margins, centrally finely longitudinally carinate, anterior margin truncate and not extending beyond eyes, posterior margin angularly concavely sinuate; scutellum a little longer than broad at base; abdomen above with the comnexivum strongly broadly upwardly ridged; legs long and slender, posterıor tibise with two spines, posterior tarsi long, first and third joints subequal in length; tegmina long and narrow, slightly more than three times as long as broad.

Type, $N$. ocellata, Walk.
The peculiar structure of the pronotum, with the pointed vertex and long narrow tegmina, are the salient characters of this genus.

## Neosphenorhina ocellata.

Sphenorhina ocellata, Walk. List IIom. iii. p. 693 (1851).
Hub. Venezucla.

## Tomaspisina, gen. nov.

Vertex about as long as broad, rounded in front, transversely impressed at middle: ocelli somewhat near together at about one-third from base; pronotum about half as long as the breadth between the humeral angles, a little convexly gibbous at hase and deflexed towards head, anterior lateral margins moderately ampliate and reflexed, very slightly rounded, almost straight, much shorter than posterior lateral margins, which are concavely simuate, anterior margin straightly truncate, posterior margin profoundly sinuate before scutellum, centrally longitudinally carinate; scutellum longer than broad, the apex acuminate ; face broad, deffected to an obtuse point and then truncately deflected to base of clypeus; rostrum reaching the intermediate coxa; tega ina about two and a half times as long as broad, the whole surface, excepting central base, very robustly and prominently reticulately reined; wings ample; posierior tibiæ with a single long spine beyoud middle.

Type, T. frontalis, Walk.

## Tomaspisina frontalis. <br> Sphenorhina frontalis, Walk. Ins. Saund., Hom. p. $\varepsilon 9\left(18 \varepsilon^{\circ} \mathrm{N}\right)$ ).

Hab. Colombia.

## Neomonecphora, gen. nov.

Allied to Makonaima; vertex similar in structure, but the central longitudinal carination restricted to the basal half, and the lateral margins before eyes with their edges not ridged and upwardly raised, ocelli placed a little nearer base; face neither centrally ridged nor deflected to a more or less acute point, but evenly rounded to elypeus; scutellum not longer than broad and discally strongly foreately depressed; rostrum scarcely passing the anterior coxæ; abdomen above not centrally raisel, but broad with a longitudinal incised
line on each lateral area, and slightly longitudinally ridged before the connexivum, which is broad and distinct ; posterior femora less longly and strongly sulcate beneath, posterior tibire slightly not considerably longer than the femora as in Makonaima, and with a single spine beyond the middle; tegmina three times as long as broad, not prominently arched at base.

Type, N. insignis, Dist.
The large and broad vertex is the character which principally allies this genus to Makonaima.

## Neomonécphora insignis, sp. n.

Vertex and pronotum brownish testaceous; scutellum, abdomen above, body beneath, and legs black; face and lateral margins of prosternum brownish testaceous; tegmina brownish ochraccous, apical half of costal area, apical margin narrowly centinued to apex of clavus, and a rounded sub)costal spot before middle black, posterior margin of clavus piccous brown; wings fuliginous; pronotum distinctly broadly foveately depressed on each side of anterior area, its anterior lateral nuargins somewhat broadly reflexed; scutellum somewhat faintly transversely striate, the disk very strongly foveately depressed; other structural characters as in generic diagnosis.

Long., excl. tegm., $f 15 \mathrm{~mm}$.; exp. tegm. 40 mm .
Hab. Brazil (Fry Coll., Brit. Mus.).

## Makonama, gen. nov.

Vertex as long as breadch between eyes, centrally longitudinally carinate, transversely impressed before the eyes, the lateral margins before eyes lobately convex, their cdges ridged and raised upwardly, and somewhat abruptly separated from the apical margin, which is broadly transversely convex, and also distinctly separated from the lateral margins of the central area or lobe, the margins of which are ridged ; ocelli placed on each side of the central carination at less than one-third from base; face somewhat globose, compressed, centrally longitudinally ridged, deflected in front to a more or less acute point, and then obliquely directed backward to the base of the clypeus, which does not quite reach the anterior coxx; pronotum about as broad between the lateral angles as its length and that of vertex taken together, rounded and somewhat gibbous on basal area and then suddenly and obliquely deflected towards head, the anterior lateral shorter than the posterior lateral margins, the former
convex, the latter obliquely sinuate, and both ridged, the lateral angles obtusely subprominent, the anterior margin truncate, the posterior margin concavely sinuate before scutellum, which is considerably longer than broad, discally foveately depressed, strongly transerersely striate, its apex long and attenuate; rostrum just or almost reaching the posterior coxie ; abdomen above centrally raised, the lateral areas deflected on each side, the comnexivum broad and distinct; legs moderately long and robust, the posterior fomora strongly longitudinaily suleate bencath, posterior tibise considerably longer than the femora and with a single long spine beyond the middle, posterion tarsi very long, third joint longest, as long or only a little shorter than first and second together ; tegmina about or only a little more than twice as long as broad, costal margin arched at base and convexly deflected to apex, which is romuded, and densely, evenly, fincly punctate; wings long and ample, about threefourths the length of tegmina.

Type, M. rivularis, Dist.

## Makonaima rivularis, sp. n.

Tertex dull reddish, the lateral margins before eyes bright reddish ochraccous; pronotum piceons, the lateral and posterior margins and a central longitudinal carination bright reddish ochraceous; scutellum dark purplish, its apical third bright reddish ochraccous; body bencath and legs purplish brown, the abdomen darkest ; a central longitudinal fascia to face and posterior margin to metasternum bright reddish ochraceous; tegmina piccous, with small linear red-dish-ochraceous spots, about seven arranged in longitudinal series beneath costal area,-two subapical, two above and beyond clarus, and a longer linear spot near middle of upper claval margin; wings dark fuliginous, their extreme bases carmine-red ; pronotum finely granulose and punctate, ceutrally longitudinally carinate, the carination not extending to base ; scutelhm coarsely transversely striate, the disk broadly ovately depressed, the apes longly attenuate; scutellum raching the posterior coxix ; tegmina strongly arched at base.

Long., excl. tegm., 17-18 mm.; exp. tegm. 48 mm .
Hab. Peru; Ecuador, Cuenca (Brit. Mus ).
Makonaina circumducta, sp. n.
Piceous; rertex with the lateral areas in front of eres and a spot at aper, pronotum with the lateral and posterior
margins and the contral longitudinal carination, apical third of scutellum, abdominal anal appendages, central longitudinal fascia and aper to face, tegmina with a small spot a little berond base, and a fasciate looped line commencing about one-third from base below costal area, continued subapically and then backwardly above clavus to less than one-third from base, and extreme base of wings, reddish och-raceous or pale sangumens: vertex with the central longitudinal carination rery distinct ; face moderately compresed, contrally longitudinally ridged, deflected in front to a more or less acute point and then obliquely directed backward to hase of clypeus ; rostrum reaching the posterior coxe ; pronotum fincly rugulose and punctate, with a central longitudinal carination not reaching base; scutellum strongly transwerely striate, the diik broadly ovately depressed; posterion tibie with a single long spine beyoud middle; tegmina strongly arched at base.

Long., excl. tegm., 15 mm. ; exp. tegm. 40 mm .
Hab. Bolivia, Yungas de la Paz.
Korobona, gen. nov.
Alliced to Makonama, from which it differs as follows :The lateral mergins before eres are lobate and subangulate, but not convex, and are distinctly ridged and continued backwardly to base at inner margins of eves ; face subglobose, flat, not compressed, and evenly directed from base to clypeus; pronotum with the anterior lateral and posterior lateral margins about equal in length; posterior tibise with a moderately long spine beyoud muddle and a very short spine near base, posterior tarsi long and robust, the apical joint shorter than first and second joints together ; tegmina short and narrow, about two aud a lalf times as long as broad; wings small and narrow ; abdomen above with a prominent basal transverse foreation on each side of apex of scutellum.

Type, K. lineata, Dist.

## Korobona lineata, sp. n.

Black ; pronotum with the lateral margins (broadly) and a central longitudnal carination, abdomen above with two central basal transverse foreations (one on each side of apex of scutellum), and a central longitudinal fascia to tegmina (neither reaching base nor apes) pale luteous; face and clypeus reddish testaccous; pronotum densely finely wrinkled and punctate, the central carination prominent, commencing at base but not reaching anterior margin, the anterior lateral
margins laminately reflexed; scutellum transsersely striate and discally broadly ovately depressed, its apex mutilated in typical specimen; abdomen shining indigo-black, above prominently centrally ridged, and laterally o liquely deflected fon each side, the connexivum broad and distinct, the margins of the latter longly pilose; legs pilose and robust ; wings short, little more than half the length of tegmina, pale fuliginous, with the veins darker.

Long., excl. tegm., 16 mm . ; exp. tegm. 35 mm .
Hab. Brazil? (Brit. Mus.).
The specimen on which this genus and species are founded is contained in the collection of the late Alexander Fry, and which was bequeathed to the British Musemm. All the Rtynchota in this collection were from Brazil.

Korobona conspicua, sp. n.
Vertex black, the ocelli reddish; promotum dull testaceonsred, two curved black spots near anterior marsin (one on each side of the central carimationi) and two piceons (curved fasciae each extending from the anterior black spots parallel to the eentral carination, looped at base, conti:ued along the posterior lateral margins and terminating hefore the humeral angles; scutellum, abdomen above, body bencath, and lems more or less black, the abdomen above shining bluish black, with the transverse basal foveations pale luteous; face, clypeus, and lateral margins of prosternum pale sanguineons, with a longitudinal fascia extending from base (where it is narrowest) beneath the costal area to near aper and attached to two fused inwardly directed spots on apical margin, and two discal longitudinal spots (one above apical half of clavus, the other above the nest longitudinal vein), piceous; wings hyaline, fuliginous on basal and marginal areas, and with the veins black; pronotum fincly wrinkled and obscurely punctate, with a distinct central lougitudinal carination almost extending to base and apex, the anterior lateral margins slightly, the posterior lateral margins very strongly sinuate; scutellum strongly transversely striate, its disk broadly, ovately, moderately depressed ; face as in generic diagnosis; rostrum passing the intermediate coste.

Long., excl. tegm., 21 mm . ; exp. tegm. 51 mm .
Hab. Brazil.
I have no more precise locality for this fine species.
Mahanarva, gen. nov.
Head robust, subtriangular, about as long as the breadth
between the eyes, the lateral and apical margins ridged and also strongly centrally longitudinally carinate, finely transversely impressed before cyes and obliquely impressed on each side of occlli, which are placed close together at about oue-fourth from base, divided by the central longitudinal ridge; face very prominent, slightly compressed, convexly defiected downwards to an obtuse point, below which it is obliquely contimued to the clypeus, which reaches the anterior coxa; rostrum about reaching the intermediate coxa; pronotum more or less broadly obtusely ridged bitween the posterior angles and then deflected towards the head, centrally fincly longitudinally carinate, the anterior margin straight, the anterior lateral margins oblique, the posterior lateral margins concavely obliquely sinuate, the posterior margin strongly concavely sinuate before the scutellum, which is about as long as lriad at base, the apex longly attenuate; legs somewhat robust, posterior tibie with a prominent spine beyond middle and a smaller spine near base; tegmina a little more than twice as broad as long, their costal margins convex, their apices rounded, the veins on apical area reticulate and very prominc:it; posterior tarsi very long, the basal joint slightly shorter than second and third joints together.

Type, M. indicata, Dist.
The structure of the vertex and face is the principal char cteristic of this genus; looking at the vertex from an oblique position, the base of the face is distinctly visible above.

## Mahanarva indicata, sp. n.

Vertex, pronotum, scutellum, face, sternum, and legs very dark olivaceous; ocelli, base of rostrum, coxæ, extreme bases and apices of femora, apices of tibire, basal joint of posterior tarsi, and all the claws sanguineous ; abdomen above very dark purplish red, beneath piceous, both surfaces more or less cretaceously tomentose ; tegmina pale chocolatebrown, a narrow, obscure, paler, short longitudinal streak at base and two small sanguineous spots on apical area (nue near costal the other near inuer margin) ; wings pale fuliginous, the veins piceous, the extreme base sanguineous, ontwardly suffused with black; vertex, pronotum, and scutellum thickly, finely, ochraceously pilose, vertex and pronotum thickly punctate, the latter centrally, longitudinally, finely, and somewhat obscurely carinate, with two foveate spots on each side of disk, between and a little in front of which are two contiguous, transverse, short impressions; scutellum
ovately depressed on disk and transversely striate; other structural characters as in generic diagnosis.

Long., excl. tegm., 10 mm . ; exp. tegm. 23 mm .
Hab. Brazil (Brit. Mus.).
There is no more precise locality obtainable for this species, which was presented to the British Museum in 1868 by the late W. Wilson Sanders. It may therefore have been contained in the collections made by Bates and Wailace on the Amazons.

## Mahanarva unifurmis, sp. n.

Vertex, pronotum, scutcllum, face, and body beneath picenus-hlack, with a slight olivaceous tint; legs piecomsbrown; tegmina uniformly pale chocolate-brown, thickly, shortly, thely, palely pilose; vertex as in gencric diagnosis, the ocelli ochracous; face downwardly deflected but not terminating in such a distinctly obtuse point as in M. imelicuta; pronotiom thichly, finely, transersely wrinkled, improsed as in . M. imdicuin, ceintrally, finely; longiturlinally carinate, the carination not reaching the anterior margin; scutellum orately impressed on disk and transversely striate.

Long., incl. tegm., $9 \frac{1}{2} \mathrm{~mm}$.
Hub. Ecuador; Paramba and Cachabé (Rosenberg, Brit. Mus.).

Cousiderably smaller than V. indicuta; face less pointed, pronotum more wrinkled and less punctate, differing also by the more uniform coloration and alssence of sanguineous markings.

## Kanaima, gen. nov.

Yertex very large and broad, slightly longer thau space between eres, transverscly impressed above and between the insertion of the antenne, before this impression broadly convexly rounded, finely, centrally, longitudinally carinate, the ocelli somewhat close together, divided by the carination, and placed at less than one-third from base; face globose, oblong, its disk somewhat broadly flattened and evenly depressed to base of clypeus, transversely striate, and centrally, longitudinally, finely ridged; clypeus extending to the anterior corx; rostrum slightly passing the intermediate coxe; pronotum about trice as broad as long, strongly foreately impressed on anterior disk, the anterior margin truncate, the anterior lateral margins convexly oblique, posterior margin truncate before scutellum, which is about as long as broad at base, its apical area attenuate; legs moderately robust, posterior tibie with two strong spines (one near base
and the larger a little beyond middle), posterior tarsi robust, first joint long (second and third joints mutilated in type) ; tegmina about two and a half times as long as broad, moderately narrowed towards apices, which are rounded, apical areas with the veins reticulate and prominent.

Type, K. katzensteini, Berg.
Allied to Mahanarva, vertex larger and of different shape and structure ; posterior margin of pronotum truacate, \&ec.

## Kanaima kutzensteini.

Tomaspis katzensteinii, Berg, Hem. Argent. p. 233 (1879).
Hab. Argentina.
XXIII.-On the Characters and Affinities of "Desmalopex " and Pteralopex. By Knud Andersen.

## The Differential Characters of "Desmalopex."

The fruit-bat described by Temminck, fifty-six years ago, as Pteropus leucopterus* has recently, by Niller, been made the type of a distinct genus, Desmalopex $\dagger$, stated to differ from Pteropus by a series of cranial and dental characters. Pteropus leucopterus appears to be rare in collections, the only specimens recorded in literature being the type in the Leyden Museum (slightly immature) and two slins with skulls in the British Museum (adults, one of them described by Gray as "Pteropus clienensis" $\ddagger$ ). I have carcfully tested all the differential characters of Desmalopex pointed out by Miller on these three skulls of Desmalopex and the whole British Museum series of skulls of Pteropus, representing

* Temminck, Esq. Zool. pp. 60-61 (18:3) ; type locality unknown, "l'on présume une des îles Philippines."
+ Miller, 'Families and Genera of Bats,' p. 60 (29 June, 1907).
$\ddagger$ Gray, 'Catalogue of Monkeys, Lemurs, and Fruit-eating Bats,' p. 111 (1580). This specimen came to the Museum from Fubert Fortune, who, from the spring of 1843 to late in 18, th, travelled in the northern provinces of China as a collector to the Horticultural society of Londom; hence it was, very naturally, believed by (iray to be from China. But the fact was apparently overlooked that Fortume also made an excursion to Luon (January to early in March, 1845; see his 'Three Years' Wanderings in the Northern Provinces of China, pp. :32-345, 1847): When to this it is added that no species of Plerome is linown to nocur in Chima, and that the type of Pt. chimensis differs in no esseutial characters from the type of Pt. lencopterus, there can be no rasomable doulit that the former was in reality obtained by Furtune during his stay in Luzon.
nearly all species known, and arrived at the conclusion that Desmalopex cannot be separated from Pteropus. It is fair to add, however, that two or three years ago, when Miller was studying the British Museum collection of bat-sknlls for his revision of the genera of bats, the series of Pteropus skulls was much less complete than now; since then all the species of Pteropus have been worked out for the 'Catalogne of Chiroptera,' and the number of skulls now available for examination is more than four times as large. Niller's opportunities for verifying the supposed differential characters of Desmalopex were therefore much less favourable than they would be now.

The characters of Desmalopere given hy Miller (here printed between inverted commas), and my comments thereon, are these :-
(1) "Like Pteropus; but skull with broader rostrum aud palate."-In no small number of species of Pteropus (c. g. Pt.nancaiensis, samoënsis, anctianus, pselaphon *, tuberculatus, pilosus, insularis. phaocephalus, lombocensis; anong the larger forms $I^{\prime} \%$. melamoporyon) the rostrum is quite as broad as or even broader than in Pt. leucopterus.
(2) "Orbits directed slightly more upward."-The orbits of Pt. lencopterus are not directed more upward than in certain other species of Pteropus, e. g. Pt. campyrus and giganteus $\dagger$.

[^35]The above are the only cranial characters of Desmalopex given by Miller; all the other characters (numbers 3-9, infrà are taken from the dentition.
(3) "Upper incisors subequal, distinctly larger than in Pteropus, the cross section of the crown nearly one-third that of canine, the cingulum produced into a noticeable shelf posteriorly." -In Pt. samuënsis, anetiamus, pselaphon, pilosus, and tuberculatus the upper incisors are fully as large as, if not larger than, in Pt. leucopterus, and at least in the three last species the cingulum is quite or very nearly as broad as in Pt. lencopterus; if there is any difference in the development of the cingulum, in favour of Pt. leucopterus, it is certainly infinitesimal.
(t) " Lower incisors very unequal, the crown area of the outer nearly one-half that of canine, that of the iuner scarcely more than one-half [probably a slip for one-fifth] as great."-In a majority of species of Pteropus $\mathrm{i}_{2}$ is about once and a half, twice, or twice and a half the bulk of $\mathrm{i}_{3}$, but the contrast in size is in some species much greater, $i_{2}$ being sometimes four, five, or six times as stout as $\mathrm{i}_{1}$. In Pt. leucopterus the disproportion is due chiefly to an increase of $\mathrm{i}_{2}$; the same is the case in Pt. samoënsis, anetianus, pilosus, and tuberculatus, in which $i_{2}$ is from three to four times the bulk of $i_{1}$; in Pt. lombocensis (and a few other species) the increase of $i_{2}$ is combined with a distinct reduction of $i_{1}$, making $i_{2}$ varying from four to six times the bulk of $i_{1}$, and thus producing a disproportion even larger than in Pt. leucopterus.
(5) "Small upper premolar well developed, not deciduous, its diameter nearly lialf that of upper incisor, its crown flat." -The vanisling p' is a trifle less reduced than usually in Pteropus, though the difference is exceedingly small indecd between Pt. leucopterus and certaiu specimens of Pt. lombucensis, in which $\mathrm{p}^{2}$ has the crown slightly but distinctly diffierentiated from the shaft. Whether $\mathrm{p}^{2}$ is really persisten in Pt. leucopterus is impossible to decide on the available material, it would require a much larger series; all that can be said is that it is present in the only three

[^36]skulls known, one of which is, however, immature, while the teeth of the two other skulls are not much worn ; on the other hand, in all the (seven) skulls I have seen of Pl. lombocensis $\mathrm{p}^{\prime}$ is present, though some of these skulls have much-worn tecth. It is quite common to find this rudimentary tooth persistent even in aged specimens of Pteropus.
(6) "Small lower premolar relatively larger than in Pteropus, but smaller than in Pleralopex, its outer edse raised but not distinctly cuspid te."-lt is a general rule in Pteropus that an increase in the size of $\mathrm{i}_{2}$ is accompanied by an increase in the size of $p_{1}$; compare, for instance, I't. lombocensis, sammïinsis, anetianus, pselnphon, pilosus;, tuberculatus. Pt. leucopteris, follows the same rule (as does also P'icralopect), and $p_{1}$ is not relatively larger in $P /$. lencopterus than in Pt. lombocensis, samoënsis, cunctituns, and pilosus. In structure it does not differ from the typical Pteropine p. $p_{1}$.
(7) " $\mathrm{pm}_{3}$ shows no trace of curp on immer side."- As well known, the structure of a typical Pteropine molar is this: a longitudinal groove flanked by higher onter and lower inner ridge. But in the anterior large premolar above and below ( $p^{3 \prime}$ and $p_{n}$ ) the onter ridge takes more the form of a high acutely pointed cusp, the imer ridge of a lower pointed cusp, and both are anteriorly closely approximated, sometimes completely fused. A fusion of the outer and imer cusps, perfectly similar to that seen in $1 \%$ of $P$. leucupterus, is shown br a considerable number of species of Pteropus, and in some species, c. g. Pt. papuamus, scapulutus, and woodfordl, the fusion of the cusps is decidedly more complete than in Pt. leucopterus.
(8) "Molars, both above and below, subquadrate in outline, the length of the crown never conspicuonsly greater thau the width ( $\mathrm{m}_{\text {. }}$ [obviously a misprint for $\mathrm{m}_{1}$ ] and $\mathrm{m}^{2}$ not clongated as in Pteropus)."-In species of Pteropus with perfectly unmodified dentition the molariform teeth, particularly $\mathrm{mi}^{\mathrm{i}}$, are conspicnously longer than broad; in Pt. lencopterus they are only one-fourth or one-third longer than broad: expressed in other words, they are shorter but not narrower than usual. It is quite natural that this peculiarly shortened form of the cheek-teeth of Pt. leucopterus attracted the attention of Mr. Miller ; it is, in fact, not precively matehed by any other Pteropus. But P't. leucopterus is in this respect approached by Pt. insularis, pheocephhtus, macrot is, épularius, poliocephalus, papuanus, and neohibernicus, in all of which the molariform teeth are shorter than usual. And a modification of the ontline of the cheek-teeth much greater than that shown by Pt. lincopterus is found in I't. personutus,
scapulutus and woodfordi, in which the teeth are not ouly much shortened but excessively narrow, as in the Macroglossi. It would be hopeless to "split" the genus Pteropus on differences in the general outline of the cheek-teeth; all modifications lead through numerous transitional stages back to the typical Pteropine molar.
(9) "Lower molars peculiar in that the ridges of $m_{1}$ and $m_{2}$ are each divided into two low but distinct rounded cusps. The quadritubercular form resulting from this is very noticeable in $\mathrm{m}_{1}$, less so in $\mathrm{m}_{2}$." - I am probably not mistaken when I consider this to be, from Miller's point of view, the chicf character of his "Desmalopex." It will be necessary, therefore, to make sure if Pt. lencopterus is not, perhaps, in this respect as in all others very closely connected with other species of the gecius. In the type of "Pteropus chinensis" (=leucopterns) there is a shallow but distinct transverse depression in the outer and inner ridge of $m_{1}$, indicating a begimning subdivision of each ridge into two incompletely differentiated rounded tubercles; the depressiou is still shallower in the outer than in the inner ridge; in $\mathrm{m}_{2}$ it is, in both ridges, exceedingly shallow, the "quadritubercular" structure of the tonth therefore only detectable on very close examination. In the other skull of Pleropus leucopterus ( 62.2 .1 .14 .3 ) I fail to discover the slightest trace of a depression in the outer ridge of $m_{1}$, while in the imer ridge it is present, though less distinct than in the other skull; in $m_{2}$ a slight depression is present in the inner ridge and barely detectable (at least with a lens) in the outer ridge. It should be noted that in both skulls the depression is more distinct in $m_{1}$ than in $m_{2}$, and more distinct in the inner than in the outer ridge. In all the skulls I have seen of Pt. psel(uphon (ten) the "splitting" of the inner ridge of $m_{1}$ is either as distinct as or (in some skulls, decidedly more distinct than in Pt. lencopterus, and a similar, but much stronger, splitting of the inner ridge is seen in $\mathrm{p}_{1}$; the inner ridge of $\mathrm{m}_{2}$ is simple, as are also the outer ridges in all teeth. On close examination of a few skulls of Pt. samvënsis and one of Pt. pilosus I find a faint depression in the inner ridge of $p_{4}$, correspouding in position to the deep groove in $p_{4}$ of Pt. pselaphom. We have thins these four progressive stages: a majority of species of Pterorias, ridges of luwer molariform teeth simple; $P$ 't. samuënsis and pilosins, a slight depression in inner ridge of $p_{1}$, suggesting an initial stage towards a splitting of the rivige into two tubercles; Pt. pselaphon, inner rillges of $\mathrm{p}_{ \pm}$and $\mathrm{m}_{\mathrm{k}}$ rery distiuctly subdivided into an anterior and posterior

Aim. \& Mag. N. Hist. Ser. 8. Vol. iii. 15
portion ; Pt. leucopterus, distinct depression in inner ridges of $\mathrm{m}_{1}$ and $\mathrm{m}_{2}$, and, at least sometimes, in outer ridges of same teeth. When to this it is added that Pt. pilosus (Pelew Islands), which in this respect marks an intermediate stage between the typical Pteropine dentition and that of Pt. ${ }^{p}$ selaphon (Bonin Islands), is the closest known relative of Pt. pseluphon, then the evidence seems to me conclusive. This more or less incomplete, or, if preferred, more or less complete, splitting of the lomgitudinal ridges of certain cheek-teeth may be used as a specific character (though even as such it is not of much practical use), but it is certainly not of generic importance.

Conclusions.-Pl. leucopterus accords with the typical * species of the Pt. pseluphongroup (Pt. pselaphon, pilosus, tuberculatus) in the following characters:-(1) The general shape of the skull ; (2) the broad rostrum ; (3) the strong supraorbital processes ; (t) the heary premaxillie ; (5) the large upper incisors; (6) the musually broad cingulum of the upper incisors ; (7) the enlargement of $i_{2}$; ( 8 ) the heavy canines, with unusually broad cingulum, the edge of which shows a pronounced tendency to split into separate rounded tubercles; (9) the large $p_{1}$; (10) the heary posterior basal ledges of the molariform teeth above and below; (11) the tendency to a splitting of the ridges of some of the lower cheek-teeth; ( $1:$ ) the distribution of the fur (tibixe densely clothed above); (13) the size and form of the ears; (14) the general size of the animal. The only noteworthy peculiar chatacters of I't. leucopterus are, in fact, the shortening of the check-teeth (in which respect it is, however, approached by Pt. insularis and pheocephains, both allied to Pt. pselaphon) and perhaps the paler colour of the fur (the three specimens linown are faded). In the face of this evidence I have not the slightest hesitation in saying that Pt. lenconterus, far from constituting a distinct genus, is simply a Philippine representative of the Pt. psela, hon group. Pt. pselaphon inhabits the Bonin Islands, Pt. pilosus the Pelew Islands, the habitat of Pt. tuberculatus is unknown, but may, not unlikely, be the Mariannes, so that also the geography is in favour of this conclusion.

## The Affinities of Pteralopex.

Desmalopex, Miller writes (t.c. p. 60), " is intermediate between Pteropus and Pteralopex, though nearer the former. In the broadened rostrum and slightly upturned orbits the skull distinctly suggests Pteralopex, while the same tendency

[^37]is shown by the form and relative size of the incisors, the well-developed small upper premolar ["upper" a slip for lower?], the squarish outliue of the molars, and the extra cusps of $m_{1}$ and $m_{2}$."

In the foregoing pages I have endeavoured to show that "Desmaloper,"," i. e. Pt. leucopterus, cannot be separated from Pteropus. But I perfectly agree with Miller that I't. leucopterus in certain respects distinctly foreshadows Pteralopex, only I must add that this is the case also with the other typical members of the Pt.pselaphon group, viz. Pt. pselaphon, pilosus, and tuberculatus, and that this group is arain closely connected with the Pl. samoënsis group (Pt.namuiensis, samoënsis, anetianus). The following review of all the essential characters of Pteralopex will, I think, place these suggestions as to a rather close relationship between Pleralopere and the Pteropus pselaphon group on a firmer basis :-
(1) General shape of skull Pteropine, on the whole nearest that of the short, broad-faced, heavily-built, strongly-crested skulls of Pt.pselaphon, pilosus, and tuberculatus.
(2) Rostrum short and very broad. In both characters rather closely approached by all species of the Pt. pselaphon and samoënsis groups, but the rostrum of Pteralopecs is relatively broader anteriorly, no doubt owing to the excessively heavy upper canines.
(3) Premaxilla heary, as in all species of the Pt.pselaphon group.
(4) Postorbital processes of frontals strong at base, very long, quite or nearly reaching zygoma; postorbital processes of zygoma small. In all species of the P't. pselaphon group the upper postorbital processes are heary at base and very long, the lower processes small or practically undeveloped; if, as is the case generally in Pt. leucopterus and occasionally in Pt. pselaphon, the orbital ring is complete behind, it is therefore formed almost eutirely by the upper processes, as in Pteralopex.
(5) Coronoid process of mandible high, very broad, stecply ascending (front margin almost at right angles with alveolar border), angular process unusually prominent, rami deep, gonys low (vertical extent), broad, and more steeply ascending than usual. Precisely all the same characters are found in the mandibles of Pt. pselaphon, pilosus, and tuberculutus; the mandible of Pt. leicopterus is weaker, coronoid more sloping, angular process less developed, gonys more typical Pteropine.
(6) Upper incisors very large. The nearest approximation to this in the gemus Pteropus is found in the species of the P't. pselaphon group.
(7) Cingulum of upper incisors rery broad. As in Pt. pselaphon, tuberculatus, and leucopterus.
(8) Great enlargement of $\mathrm{i}_{2}$ combined with some reluction of $i_{1}$, making the contrast in the sizes of these two teeth greater than in any Pteropus. A disproportion between $\mathrm{i}_{2}$ and $\mathrm{i}_{1}$ is seen already in Boneiu, a genus closely allied to the primitive Rousethus; the character is further developed in Pteropus (which no doubt originates from a Rousetlus-like form), either by an increase of $\mathrm{i}_{2}$ or by this combined with a reduction of $i_{1}$; and the reduction of $i_{1}$ culminates in the complete disappearance of this tooth in Styloctenium and Dobsomin (both geuera allicd to Pteropus). This character of Pteralopex is therefore only an excessive development of a tendency already present in all the related genera. The numerous species of Pteropus show all intermediate staces, from an $i_{2}$ which is only about ouce and a half the bulk of $i_{1}$, to an $i_{2}$ about six times the size of $i_{1}$. The nearest approximation to the enormous disproportion of these teeth exhibited by Pteralopex is seen in the species of the P' pselaphon, samoënsis, and lombocensis groups.
(9) Upper canines peculiar in the following points :(a) cingulum very strongly developed, its edge split into separate tubercles; the same is the case in Pt. pselophoon, pilosus, and tuberculatus, less distinetly in Pt. lencopterus; the tubercles of the cingulum in P't. pilosus exactly correspond in number and position to those of Pteralopex, only they are slighty smaller: (b) a strong secondary cusp halfway up the hinder colge of the canine; the only species of I'teropus possessing a secondary cusp in the uper canines is 't. tuberculatus (of the pselaphion group); the cusp in this species is much smaller than, but similar in position to, that of Pleralopex.
(10) Cingulum of lower canines broad, forming a conspicuous shelf posteriorly. As in the Pt. pseluphon group.
(11) $\mathrm{k}^{3}, \mathrm{p}^{4}$, and $\mathrm{m}^{\prime}$ modified as follows: - (a) crown short and broad, subsquarish in outline: (b) hinder (trausserse) border of tecth conspicuously raised, front border similarly raised: (c) owing to the shorteniug of the teeth and the sharply raised anterior and posterior borders, the usual " longitudinal ridges" of a Pteropus molar are become much shortened (in antero-posterior extent) so as to form two pointed cusps situated opposite each other, the one on the labial, the other on the liugual side of the tooth, a little in front of the middle. The structure of the Pteruloper molar is very easily derived from the molar structure of any species of Pteropns, but it is most likely, of course, that it has origiuated from a tooth in which already the posterior basal ledge (posterior
border) was more developed than usual. Such is the case in the Pt. pselap,hon group (as well as in the related Pt. stmoe isis group), and in Pt. psel(ophon and allind species also the anterior border (cingulum) of $\mathrm{p}^{3}$ and $\mathrm{p}^{4}$ is distinctly raised, purticularly in $p^{3}$. Of the furur known typical species of the pselnplosin group, $P^{\prime} t$. leucopterus shows decidedly the nearest app:oximation to Pterulopex in the general aspect of the upper cheek-teeth; the crown is so much shortened as to be nearly subsquarish, the anterior and posterior bordurs of each tooth slinhtly but quite distinctly raised, and the "longitudimal ridges" more shortened and cusp-like than usual. The only additional modifications required to transform an upper molar of Pt. leucopterus into that of a Pleralopes is a further emphasizing of the changes which already have taken place in the passage from a typical Pleropus molar to that of a Pt. leucopterus, viz, a slight further shortening and broadening of the tooth and a much stronger development of thie anterior and posterior borders. The difference in this respect between Pt. lencopterus and Piercaloper is unquestionably ouly one of degree.
(12) $\mathrm{p}_{4}, \mathrm{~m}_{1}$, and $\mathrm{m}_{2}$ morlified as follows:-(a) crown shortened and broadened, though not quite to the sume degree as in the upper teeth: (b) inner cusp unmodified (not divided), outer cusp bifid (i.e. the tip of the originally simple cusp divided into two cusps by a rather deep groove, which, however, is more conspicuous and goes decper down on the inner than the outer side of the ridge): (c) posterior basal ledge very strong, peculiarly oblique, being much more developed on inner than outer side of teeth; anterior basal ledge undeveloped as in Pteropus generally. All characters much less developed in $m_{2}$ than in $p_{4}$ and $m_{1}$. - A begimuing splitting of the ridges (cusps) of the lower cheek-teeth is already seen in Pt. pselaphon and leucopterus (see suprì). In Pt. pelaphon the character is even strongly pronounced in the inner ridge of $p_{4}$, very distinct also in that of $m_{1}$; in Pt. leucopterus it is distiuct in the inner ridges of $m_{1}$ and $\mathrm{m}_{2}$, less so, or occasionally scarcely detectable, in the outer ridges of the same teeth. The still stronger splittiug of the outer ridges of $\mathrm{P}_{4}$ and $\mathrm{m}_{1}$ of Pteralopex: is therefore only a further development of the tendency ahready well pronounced in Pt. pselaphon and leucopterus. But one difference should be noticed; whenever these characters and tendencics are present in the $P t$.pseluphon group, they are either entirely restricted to the inner cusp of the lower cheek-tecth or at least more pronounced in the inner than in the outer cusp; but in Pteraloper the character is, so to say, shifted from the inner cusp, which is absolutely undivided, to the outce:
cusp.-Viewed in profile, $p_{4}, m_{1}$, and (much less so) $m_{2}$ of Pleralopex present three cusps behind each other, viz. two higher anterior (the bifid onter (ensp) and a low posterior. This latter is not a cusp peculiar to Pteralopex: it is homologous to the postero-extermal cusp arising from the posterior basal ledge in all species of Pteropus which have this ledge conspicuously developed.
(1:3) Distribution of fur (tibise densely clothed above). In all details perfectly as in the species of the Pt. pselaphon and samoënsis groups.
(14) Lateral membranes arising, not from the sides of the back, but from the spinal line. 'I here is no parallel to this in any known species of I'teropus (but an approximation in Pt. melanopoyon, pupuanns, and neohibernicus, in which the membranes arise closer toycther on the spinal tract than in other I'teropi ; the character has, however, probably no great taxonomic value, since Pt. papmanus and neohiliernicus belong to a group of species very different from that of which Pt. melonopoyon is a repreentative, while, on the other hand, in Pt. aruensis and keyensis, though both closely allied to Pt. melanopoyon, the position of the membranes is perfectly normal). An exact parallel is shown by Dobsomia, an aberrant genus of the Pteropus group.
(15) Lars small, hidden in the firr, so broad above as to be semicircularly rounded off. The ears are small in all species of the Pt. pstluplum and sammeinsis groups, of ten lidden in the fur, but in all species more or less narrowly rounded off above. In one single species of Pteromitis (I't. livinystomii) the cars are very similar in shape to thove of Pteralopex.
(16) Colour of fur (blackish above and bencath). As in Pt. pselaphon.
(1i) Size of animal. As an average species of the P't. pselaphon and samoënsis groups.

Summary. - All the cranial and dental characters of Pteralopert, without any exception, point back to the species of the Pt. pseluphion group, much more decidedly than to any other known bats ; all external characters, except the insertion of the membranes and the shape of the ears, point in the same dhection. From this evidence it appears safe to assmue that Pteralopen (Sulomon Islands) is a highly specialized offshoot from that branch of f'teropus which in the Bonin Islands, Pelew Islauds, Vanikoro (or Mariannes), and Philippines has developed into, respectively, Pt. pselaphoon, pilosus, tuherculatus, and lencopterus, and in the Carolines into Pt. insularis and pherocephalus. Also the habitat of Pteralopex is in favour of this conclusion.

## Group Sphæridiidæ.

## Adolopus australis, sp. n.

Compact, convex, oblong-oval, nude, shining; head and thorax reddish brown, but not quite concolorous, the back of the former and disk of the latter being suffused with dark
fuscous, the prevailing tint of the elytra, which have rufescent margins ; tibise fulvescent, the tarsi. pilpi, and anternse yellow, but the triarticulate club is infuscate, opaçue, and densely pubescent.

Head not very closely, wery fincly, yet guite definitely punctate. Thorux transverse, finely marginate, gently curvedly narrowed towards the slightly obsuse anterior angles, its sculpture not appeciably different from that of the head, with two small punctiform impressions near the base. Scutellum rather large, not quite smooth. Elytio finely punctured, with wedi-marked sutmal striee behind and several sentes of distinct punctures which, hehind and near the sides, almost form strie ; the margins, though fine, are distinct, but not at all explanate behind as in A. allulus.

Conderside subopaque, piceons, more rufescent in front; ventral segments very minutely sculptured and firely pubescent; the moderately convex subtriangular midde portion of the metasternum finely, yet evidently but mot closely punctured and a little glossy, its flanks dull and closely senfutured. Posterior femora minutels, indistanetly, and irregularly strigose, with very fow minute puncoures ; the other pairs pubescent. Tarsi very sparingly setose underneath, second joint of the posterior evidently longer than the exposed portion of the first. Prostemal and abdominal carina well developed.
A. montume most nearly resembles this species, but can be casily recognized by the numerous well-developed spaniform setie along the outer face of all the tibie, parmionarly of the intermediate pair, whereas in $A$. custoulis there are very few, and these not at all conspicuous.

Length $1 \frac{1}{4}$; breadth $\frac{3}{4}$ line.
Luvercargill. Received from Mr. A. Philpott; three specimens,

## Adolopus tibialis, sp. n.

Oblong-oval, only moderately conrex, slightly nitid, glabrous, nigrescent, tibise and elytral marwins red; tarni, palpi, and autemay yellow; club fuscous, the head and sides of thorax obscurely rufescent.

Head fincly but not closely punctate. Thorax transverse, very gradually narrowed anteriorly, finely margined, its punctuation fine, distinct, but not close. Eilytiol with sculpture similar to that of the thorax, but in addition with series of coarser punctures near the sides; none of these, however, reach the base; on the disk the serial punctures are very much fincr, those near the suthie becoming quite obsorete near the base; all are coarse at the apex, where the sutural row on each elytron become striate.

Tibice, anterior with one very small and two distinct setre along the outer edge, those on the other pairs short and indistinct.

Less convex and narrower than $A$. helmsi (1833), the aper of elytra not at all castaneous, the tibie much less evidently or scarcely at all spinose externally. The elytral margins are not expanded as in 158 and 1690 , and both of these are different otherwise.

Length $1 \frac{1}{2}$; breadth $\frac{3}{4}$ line.
Otira Gorge (Mr. J. H. Lewis) ; a single specimen.

## Group Aleocharidæ.

## Protopristus, gen. nov.

Body elongate, parallel, slender, minute.
Head suboblous, slightly but abruptly contracted near the base. with a short neck, its whole front closely and distinctly serrate. Eyes small, rather flat, placed at the sides before the middle, composed apparently of two coarse facets. Mandithes falciform, very elongate, with a long projecting central tooth inside. Anfennce rather short, implanted on the forehead, nearly equally distant from the eyes and each other, 11 -jointed ; hasal two joints stont, oblong ; joints 3-6 small, moniliform; seventh and eighth also small, transverse, slightly broader than the preceding ones; minth also transverse, rather broader than the eighth ; penultimate abruptly enlarged, twice the size of the ninth; the terminal orate, as broad as the tenth but nearly double its length; they are not perceptibly pubescent. Maxillary pulpi as long as the basal five joints of the antemæ, penultimate joint suborate, emarginate at apex, the terminal small and transparent so as to be almost invisible. Thorax with acutely prominent anterior angles, its sides slightly curvate, posterior angles obtuse. Elytica subquadiate, very short, base and apex incurved. Abdomen very elongate, longer than the rest of the body, basal four seginents transversely quadrate, about equal, with broad lateral margins, fifth and sisth elongate, seventh very narrow.

Femora stout, arched above, the posterior in the male somewhat angulate and dentate below. Tibice arcuate externally, unarmed. Tarsi 4 -articulate, basal three joints small and conjointly not longer than the terminal one; claws divergent, simple.

Coxe prominent, the anterior and intermediate contignous, the former situated very near the hind edge of the prosternum, the posterior slightly separated.

This minute member of the Staphylinidee scems to have
no group ready for its recoption ; it most nearly resembles the Prederida, but its structure forbids such an association. If placed with genera having four-jointed tarsi, its other structural characters would not accord with theirs. The labial palpi and mentum are not discerni'ble when examined with a half-inch lens in the microscope. The closely serrate front of the head resembles in miniature that of an Alcuchus.

## Protopristus minutus, sp. n.

Slender, slightly nitid, rufo-testaceons, the palpi, antem e, and tarsi flavescent; pubesecuce distinct, pale greyish yellow.

Head slightly convex, moderately fiuely but not closely punctured ; just behind each antema there is a dark, deep, but not coarse puncture. Antenuce apparently glabrous. Thorax longer than broad, rounded towarls the base, its punctuation indistinct. Elyfra shorter than thorax, base and apex incurved, somewhat rounded laterally, distinctly but not very closely punctate, the suture indistinct. Hind borly rather finely but not closely sculptured, its apical segments paler than the others.

C'uderside pale rufo-castancous, fincly punctate and pubescent.

Length $\frac{5}{8}$; breadth nearly $\frac{1}{8}$ line.
Broken River, Canterbury.
We are indebted to Mr. J. H. Lewis for having brought this fragile creature to light.

The generic description has been drawn up from a specimen specially prepared and mounted on glass, the specific from two on cardboard. Those on cardboard could not be entirely cleared from sappy matter without destroying them.

## Group Staphylinidæ.

## Quedius hilaris, sp. n.

Subdepressed, elongate; head and thorax glossy æneous black, hind body violaceous black and iridescent; mandibles red ; basal three joints of antenuse rufescent, the others opaque, fuscous, and densely pubescent; legs piccous, tarsi reddish.

Antenne just reaching base of thorax, third joint longer and more slender than second; joints $\tilde{-}-10$ suboblong, more slender at base than at apex, eleventh more prolonged apically at one side than the other. Heudt subrotundate, rather short and broad, with two distinct frontal punctures and four or five alongside each eye; there are also a few minute indistinct punctures, but at the sides and behind the
eyes these become quite distinct. Clypeus very short, iufuscate. Labrum medially emargiuate, with a membranous border beyond the setre. Eyes longitudinally oval, moderately convex and occupying more than half of each side. Thorax as long as it is broad, rounded behind; with two punctures before the middle, one larger near each anterior angle, another close to each side near the middle, and some smoller ones at the basal margin. Scutellum large. Elytra of the same length as, but rather broader than, the thoras behind, rather elosely and somewhat transversely minutely punctate-granulate and rugose, clothed, like the scutellum, for the most part with pale yellowish hairs, the suture reddish, and with three or four obscure rufo-piceous sp its on each ; apices oblique towards the suture. Hind body clothed with cinereous hairs, and here and there with small patches of yellow ones, the long setre fuscous ; it is moderately closely punctate, with stout pitchy-red styles. Male anterior tarsi strongly dilated.

Dr. Sharp's $Q$. latifions differs in having a short thorax and somewhat different sculpture.

Length $3 \frac{1}{2}-\mathbf{4}$; breadth $\frac{3}{4}-\frac{7}{8}$ line.
Broken River. One male from J. H. Lewis and another from Mr. A. Philpott, of Iuvercargill.

## Group Pæderidæ.

Hyperomma tenellum, sp. n.
Slender, elongate, shiuing, rufo-piceous; legs infuscate red, tarsi and antemæ rufo-testaceous, mandibles red.

Head evidently longer than broad, scarcely at all rounded, the frout almost smooth, the middle also nearly smooth, there being a few fine punctures only, the base and sides with moderately coarse but not close punctures, and bearmg some outstanding slender obscure greyish hairs. Eyes small, not convex. Thorax nearly twice as long as broad, obliquely narrowed near the base; on each side of the middle there is a series of distinct punctures, there are two less regular at each side, and the minute intervening punctures are almost serial. Elytra abbreviated, only about one-half longer thau broad, shoulders rounded, apices obliquely truncate towards the suture; their punctuation like that of the thorax, at each side of the disk there is one regular series, there are very few minute punctures. Abdomen elongate, finely, irregularly, and rather closely punctate and pubescent, basal four segments with thick margins, the terminal with elongate appendages.

Mandibles very clongate and strongly curved, minutely
bidentate at base, the central tooth long and stout. Labram deeply notched. Antenure finely pubencent, attaining middie of thorax, basal joint hardly as long as the following two conjointly, the terminal somewhat pointed. Basal four joints of anterior tarsi a little dilated, the tourth rather smaller than third.

Underside shining brown; head with fine hairs directed forwards, penultimate ventral sesment deeply emarginate.

Rather more elongate than $I$. duplicutnum, much darker in colour, thorax with suhparallel sides, and the median tooth of the mandibles twice as long.
$\delta$. Length 4 ; breadth $\frac{1}{2}$ line.
Timaru. One found amongst fallen leaves by Mr. Walter Lawrence Wallace.

## Group Omaliidæ.

## Omalium flavipalpi, sp. n.

Elonyate, depressed, shining, piceous; legs and apical segment fusco-testaceous; tarsi and palpi flavescent; basal five joints of antemme rufescent, the remainiug ones fuscous and opaque.

Head (eves included) rather wider than front of thorax, rather finely punctured; frontal impressions not deep, the intervening space nearly smooth, the large punctures somewhat shallow ; there are also a few rugie alungside the prominent eyes; the ocelli are reddish. Anternce with the last six joints abruptly dilated and pubescent, the terminal evidently longer than tenth, basal joint nearly twice as large as the suboval second, third shorter and broader than form. Thorax transversely quadrate, fincly margined, slightly and gradually narrowed towards the rectangular posterior angles, the anterior broadly rounded ; it is distinctly but not coarsely or closely punctured, the discoidal impressions are well marked from the base to beyond the midile, and are divided by a smooth central line which appears cariniform, the depression at each side occupies more than half of the whole length; like the head, it is sparingly clothed with slender yellowish hairs. Elytra distinctly broader and nearly twice the length of thorax, apices truncate but with rounded angles; their punctuation almost serial, they bear minute, inconspicuous, greyish setæ. Abdomen finely sculptured, its greyish pubescence slender and depressed but quite perceptible, the basal four segments broadly margined; fifth longer and narrower than fourth, not closely united with its broad margins, almost smooth on the middle, but finely and closely transverscly rugose at the sides; sixth obliquely
narrowed backwards, its extremity truncate. Tibie minutely setose.

Allied to O. spadix, more slender, not at all rufescent, more finely sculptured, and with shorter differently formed antennæ.

Length $1 \frac{1}{4}$; breadth $\frac{3}{8}$ line
Broken River (Mr. J. H. Lewrs) ; one example.

## Omalium planinarginatum, sp.n.

Elrinyute, deprewed, shining, variegate ; head pitchy red, the thorax, shoulders, abdominal margins, and terminal segment castanco-rufons, elytra piceo-fuscous, hind body castaneous; lers and palpi fulvescent, basal five joints of autemis clear red, remaining joints nigrescent and opaque.

Antenne with the thick basal joint nearly doulle the length of the oviform second, third evidently longer than its predecessor ; joints 4 and 5 mouiliform, 6-10 abruptly enlarged, laxly articulated, and transverse ; eleventh quadrate, but with a narrower false terminal articulation. Hecul abruptly contracted behind, so as to form a short neek, which is minutely transversely strigose; it is as broad, including the prominent eyes, as the front of thorax, it is finely yet distinctly but not closely punctured, except on the broad frontal impressions; the ocular punctiform forese small; ocelli rufescent. Thorax transversely quadrate, with romnded anter.or angles; it is nearly straight behind the middle, basal angles rectangular; its punctuation like that of the head, the discoidal and lateral impressions similar to those of O. Auripulpi. Eintra oblong, rather broader than and nearly twice as long as the thorax; suture smooth; their punctuation distinct and almost serial, but not so well marked near the sulbtrumeate apices. Hind body as long as wing-cases, transersely convex ; basal four segments with broad lateral margins, which, howercr, instead of being more or less elevated, are quite depressed, these segments more distinctly thongh not coarsely punctured at the sides than on the midule; on the middle of the second there are two slight rounded impressions, both of which are closely and rery minutely sculptured; the fifth is narrower, but longer than the fourth; the sixth only half the breadth of the preceding one, seventh still narrower. Tibice finely setose.
'Ile pubescence on the hind body is fine, distiuct, yellowish, but slender and inconspicuous.
'I his species is recognizable by the flattened margins of the abdomen.

ठ. Length $1 \frac{1}{2}$; breadth $\frac{3}{8}$ line.
Broken River. A single individual from Mr. J. H. Lewis.

## Omalium setipes, sp. n.

Subdepressed, slightly nitid; head and thorax red; elytra testaceous, sometimes infuscate ; hind body castancous; legs fusco-testaceous, the palpi aud basal five joints of antennee rufo-testaceous, the following joints infuscate.

Antenne stout, reaching backwards to the shoulders: third joint elongate, yet distinctly short w and more slender than first ; joints 4 and 5 about equal, oviform, lonser than broad; 6-11 enlarged and densely pubescent, sixth evidently long* than broad, seventh and eishth obconical, ninth and tenth subquadrate, eleventh somewhat acuminate; the fine grey pubescence on these joints seems to form an apical fringe on each. Head with minute coriaceous sculpture and a few fine scattered punctures; frontal foree distinct, the basal two subtriangular and well marked, the ocelli situated within these basal impressions ; just behind the antemna there is a transverse serics of fine punctures. Thorax transversely quadrate, anterior angles rounded, the posterior obtuse yet nearly rectangular ; its surface finely, irresularly, but not closely punctured; dorsal impressions rather shallow, the space between them rather broad and nearly smooth; lateral impressions angular, very shallow, and indistinct. Elytica rather broader than and twice as long as the thoras, apices rounded; rather finely and regularly punctured, rather more closely near the extremity, their pubescence incomspicnoms and scanty. Hind body apparently shorter than the elytra, which nearly conceals the basal segment; the basal four segments with broad raised margins, rather closely and distinctly punctured, the pubescence yellowish; fifth sub)truncate and nearly membranous at the extremity, the second with shallow minutely sculptured fover on the middle. Tibice evidently sctose, the intermediate subserrate.

Underside of a reddish-chestnut hue, finely punctate and pubescent; sixth veutral segment deeply concave. The basal joints of the front aud middle tarsi with very long grey setæ, the terminal joint slender and evidently longer than the basal four taken together.
O. chulmeri in general appearance wost nearly rescmbles this species.
$\sigma^{\sigma}$. Length $1 \frac{1}{2}-1 \frac{3}{4}$; breadth $\frac{1}{2}$ line.
Invercargill. Discovered by Mr. A. Philpott.

## Group Silphidæ.

Choleva nemoralis, sp. n.
Cuncex, broadly oval, moderately nitid, fuscous; head
ferruginous ; the palpi, tarsi, basal five or six joints of antemme, and hind angles of thorax testaceous; tibice sanguincous; vestiture yellowish, slender but conspicuous.

Head finely and not closely punctured. Eyes prominent. Antenue with infuscate setæ; basal joint longest, cylindric; second stouter and slightly longer than third, which is sleuder and about equal to fourth in length ; sixth more oviform thar fifth and rather shorter ; joints 7, 9, and 10 enlarged, oblong ; eighth small and oviform ; eleventh longer than tenth, its extremity pallid. Thorax transverse, of the same width as elytra at the base, a good deal curvedly narrowed towards the depressed anterior angles, base truncate; its surface distantly and obsoletely punctured. Scutellum minute. Elytra regularly curvedly narrowed posteriorly, with a wellmarked sutural stria on each, which, however, becomes o!soulete near the apex ; their sculpture consists of transverse serics of minute crenulations. Tibie straight, finely piluse, the intermediate with a few spiniform setæ.

Underside shining, piceo-fuscons; epipleuræ and last two ventral segments rufescent, sparingly clothed with slender yellowish hairs, minutely and indistinctly punctured. Front and middle coxæ prominent; the former contiguous, the latter separated by the mesosternal carina. Metasternum convex. Terminal joint of maxillary palpi elongate, tapering and acuminate.

Male.-Basal two joints of anterior tarsi dilated and emarginate at apex, third moderately expanded, fourth swall ; the intermediate and posterior simple, filiform. Thurax paler.

Most nearly related to $C$. monticola, but broader, the antennæ less elongate, joints $9-11$ shorter, and the tramsversal interstices of the elytra more shining.
f. Length $1 \frac{3}{8}$; breadth nearly $\frac{3}{4}$ line.

Broken River. One of each sex from Mr. J. H. Lewis.

## Group Trogositidæ.

## Grynoma albosparsa, sp. n.

Subdepressed, elongate, slightly shining, black, the margins of elytra and the legs piceo-rufous.

Head quite a third narrower than thorax, with coarse shallow punctures, the intervals very narrow, pubescence white. Palpi short, black. Antennee also black, slender and elongate, basal articulation thick and distinctly punctate, second subeylindrical and not so stout ; joints 3-6 slender and of about equal length, seventh shorter ; eighth and ninth equal, evidentl! broader at the extremity that at the base;
tenth elongate-oval ; they bear a few distinct dark hairs. Thorux strongly transverse, its sides molerately explanate and rounded; posterior angles not sharply defined, the anterior obtuse, apex widely incurved; its punctuation shallow, close near the sides, fiue and more distant on the disk, which therefore is more shining; the white pubesence is scanty on the middle, but thick at the sides, where there are some long outstanding hairs. Ehytra oblong, rather wider than thorax at the base; near each shonlder there are two very slight paler elevations; their punctuation is coarse, not quite serial, and the intervals leetween them are quite as large as the punctures themselves; the silvery pubescence has a tendency to form irregular patches, leaving equally irregular bare spots. Leys simple ; tarsi clougate, terminal joint as long as the basal four taken together.

Readily differentiated by the black surface and unusually elongate antennæ.

Length $2 \frac{1}{2}$; breadth $1 \frac{1}{8}$ line.
Broken River, Canterbury (Mi. J. H. Lewis) ; one.

## Promanus subcostatus, sp. n.

Oblong, subdepressed, subopaque, fuscu-rufous; the antennæ, palpi, and tarsi rufo-testaccous.

Head closely, coarsely, and rugrosely punctate. Thorar strongly transierse, of nealy the same width as the elytra, slightly broader at the base than it is in front, the sides moderately romoled, apex widely emarrinate, base medially truncate but slightly sinuate towards the obtuse angles, with explanate margins; the punctuation coarse, close, and rather shallow, but on the middle finer and distant. Scutellum with greyish pubescence. Elytra finely marginate, with nearly vertical sides bearing irregular series of coarse punctures; the discoidal sculpture con-ists of about twelve series of coarse punctures, these series very nearly regular; interstices barrow, nearly plane at the base, but becoming costifurm beyond the middle; the pubescence scanty, fine, and inconspicnous; the head and thorax bear slender yellow hairs.

Abdomen finely and closely punctured, with fine greyish pubescence, the segments of nearly equal length. Prosternal process deeply grooved at each side, the middle distmetly carinate between the coxæ. Mehasternum broadly impressed in front of the contiguous posterior cosse. Maxillary palpi rather elongate, terminal joint not at all broadly securiturm and with a well-marked furrow underucath extending from the extremity to the middle.

Considerably laper than $P$. depressus, with closer and coarser sculpture near the sides of the thorax, subcostate
elytral interstices, and differing also by the peculiar terminal jomt of the maxillary palpi. In P. auripilus the pubescence is more conspicuons and the punctures on the thoras are hardly half as coarse or numerous.

Length $4 \frac{1}{4}$; breadth nearly 2 lines.
Southland. My specimen was found by Mr. A. Philpott.
[To be continued.]
XXV.-A new Species of Pteropus from the Loyulty Islands. By Knud Andersen.

## Pteropus auratus, sp. n.

Allied to Pt. vetulus (New Caledonia), but easily distinguished by its larger ears and different colour of the fur. Forearm (type) 145.5 mm .

Ears.-Length from base of orifice 24.5 mm ., against 20 in $P t$. vetulus; greatest breadth 17 mm ., against 12. General form of ears as in the allied species.

Colour.-Back golden ochraceous clouded with brownish; individual hairs vandyck-brown at base, with long golden ochraceous-buff tips. Breast and belly rich golden ochraceous, palest (golden ochraceous-buff) at base of hairs, shading to tawny on foreneck, sides of neck, and flanks, and to tawny russet faintly sprinkled with ochraceous on chin, throat, and anal region. Mantle rich golden ochraceous-buft, this colour confined to tips of hairs, middle portion of individual hairs buff, extreme base next to skin seal-brown; colour of mantle shading gradually into tawny on occiput and sides of neck. Crown buffy, slightly darkened with brownish and shading gradually into tawny on sides of head.

Type. of ad. al. (with skull); Lifu, Loyalty Islands; collected by the Rev. S. J. Whitmee; B.M. 77. 7. 23. 1.

Remarks.-Though strikingly different in general aspect, the colour of this beautiful species is easily derived from that of the New Caledonian Pt. vetulus: the dark brown colour of the head and underparts of a Pt. vetulus is in Pt. auratus replaced by golden ochraceous or ochraceous-buff, and the dark brown of the back by mixed golden ochraceousbuff and brownish. In the single available specimen $\mathrm{p}^{1}, \mathrm{~m}^{1}$, $p_{3}, p_{4}$, and $m_{1}$ are decidedly smaller than in three skulls of $P \ell$. vetulus.

Ann. \& Mag. N. Hist. Ser. 8. Vol. ii.
XXVI.—Descriptions of Three new Freshwater Fishes from South America, presented to the British Museum ly IIerr J. Paul Arnold. By C. Tate Regan, M.A.

## 1. Cichlosoma biocellatum.

Allied to C. coryphicenoides, Heck. Depth of body $2_{4}^{1}$ in the length, length of head $2 \frac{3}{4}$. Snout a little longer than eye, the diameter of which is 4 in the lengeth of head ; interorlital width 3 in the length of head. Foid of the lower lip not continuous; jaws equal anterionly ; masillary not quite reaching the vertical from anterior ed ge of eye; depth of preorbital nearly $\frac{3}{4}$ the diameter of eye; cheek with $f$ series of scales; 8 gill-rakers on the lower pait of the anterior arch. 31 scales in a longimudinal series, 5 in a transverse series from origin of dorsal to lateral line, 41 etween lateral line and sheath at base of anterior part of solt dorsal. Dorsal XIX 9 ; origin above opercular cleft ; spines subectual from the seventh to the sisteenth, thence increasing to the last, which is $\frac{2}{3}$ the length of head; soft fin pminted, whin laid back reaching the middle of candal. Amal VIII 8. Pectoral shoiter than the head, extending to above the third anal spine. Caudal rounded. C'an lal perluucle ? ? as long as deep. Body with 8 dark cross-hars ; third and tourth joined by an uhlong blackish spot, edged with whitish, below the lateral line; in front of this a dark longitudinal band rumning forward to the eye ; a blackish ocellus on the upper part of the base of the caudal fin; vertical fins with series of dark spots.

A single specimen, 80 mm . in total length, from Nañaos, Rio Negro.
C. corrypheronoides has XVI 12-14 dorsal and VI-TII 9-11 anal rays; the spines are longer and stronger than in C. li, ocectutam, from which it also differs in coluration and in the form of the head.

## 2. Otocinclus arnoldi.

Depth of body $4 \frac{1}{2}$ in the length, length of head $3 \frac{1}{5}$. Diameter of eye $5 \frac{1}{2}$ in the length of head, interorbital wialth 2 ; snout as long as postorbital part of head; supraoccipital without median ridge, strongly elevated posteriorly, its extremity on the level of the origin of dorsal. Scutes not carinate, 25 in a longitudinal series; abdomen with 3 longitudinal series of plates. Dorsal I 7; origin above that of the pelvics; 20 adipose fin. Anal I 5 . Pectoral spine extending beyond
base of pelvics．Caudal emarginate．Caudal peduncle $2 \frac{2}{5}$ as long as deep．A rather broal dark longitudinal band along the middle of the side，ending at the base of the caudal； vertical fins barred with 3 to 5 series of dark spots．

A single specimen， 55 mm ．in total length，from the La Plata．

Aliiel to O．affinis，Steinl．，which has a median ridge on the suprao scipital and the fins．unspotter，and to（3itcotus， Regan，which has the supraoccipital less elevated，the scutes fewer，and the coloration somewhat different．

## 3．Precilia heteristia．

Depth of body about $3 \underset{2}{2}$ in the length，length of head nearly 4．Snout shorter than eye，the dameter of which is $\ddot{3}$ in the length of head；meromital width more than $\frac{1}{2}$ the length of hearl． 27 or 28 scales in a longitudinal series． Donsal 6－7；origin equidistant from end of snout and middle （ 己）or posterior part（ 8 ）of caulal fin；last two ray：，in the male，produced into long filaments．Anal 8；oriwin in arkance of that of the dorsal ；fin printed（ 8 ）or modified int，an intromittent organ which is a little shorter than the lepal（ 己）．Pectoral a little shonter than the head；pelvic fine longer in the male than in the female．Candal romeder． Olivacenus；edges of scales darker；some hackish vertical streaks on tle side；a rertically expanded blackish spot at the lase of the candal fin；male with a short blackish stripe near the upper edge of the caudal fin．

Two specimens， 35 mm ．in total length，from Para．

## The following communication was read：－

[^38](4) ? Bala Beds.-Coarse conglomerato and sandstone containitn pebbles, mainly of granite and felsite.
(3) Llandeilo Beds.
(c) Shangort Beds.-Grits and tuffs, coarse and fine, the prevalent type being a calcareous gritty tuff, in which is a series of limestone-breccias, having a maximum thickness of about 40 feet and largely formed of disrupted fragments of the underlying limestone.
(b) Tourmakeady Beds.-Compact pink, grey, or white limestones, sometimes in beds with a maximum thickness of about 30 feet, but usually represented by blocks in the Shangort Beds.
(a) Red felsite or rhyolite.-A series of flows varying much in thickness.
(2) Arenig Beds-Mount-Partry Beds.
(d) Tariable tuffs, grits, and cherts, the tuffs being seen only in the southern half of the area.
(c) Coarse quartzose and felspathic grits.
(b) Grits, graptolitic black slates, and radiolarian cherts.
(a) Coarse conglomerates, the pebbles of which consist almost entirely of grit.

A considerable series of graptolites, collecter from the MountPartry Beds, has been examined by Mi-s (i. L. Elles, D.Sc., and they prove to be of Uppler Arenig age-about the zone of Didymograptus hirumlo. The radiolaria from the same series of rocks have been studied by Dr. G. J. Hinde, F.R.S.

The most interesting and puzzling beds of the district are those of Llandeilo age. Although the limestones (Tourmakeady Beds) occur in the main as disrupted blocks in the gritty tuffs' (Sinangort Beds), the fossils indicate that there is no material difference in the age of these two deposits; and the Authors believe that, after the deposition and consolidation of the limestone, hat during the prevaleuce of the same faumal trpes as those which characterize that deposit, the limestone was broken up by roleanic explosions, and its fragments, mingled with bits of felsite and other material, were deposited as the peculiar limestone-breccias. This riew regarding their formation is held to afford an adequate explanation of the patchy development of these rocks.

The intrusive rocks are of considerable interest. They are, in the main, felsites with large quartz-crystals, and not infrequently contain augite. Some of them are certainly intrusive in the coarse Bala (?) conglomerate. A number of small but interesting intrusions of olivine-dolerite, hornblende-lamprophyre and fine-graned oligo-clase-bearing rocks are scattered throughout the district.

The appendix embodies a critical rerien of the fauna of the Llandeilo Beds of the district, and a description of several new species of brachiopods and trilobites.

## [EIGHTII SERIES.]

No. 15. MARCH 1909.

XXVIT.-Notes on Larual Trematodes*. By Wilitay Nicoll, M.A., D.Sc., and William Small, M.A., Gatty Marine Laboratory, University of St. Andrews.

During a short visit to the West of Scotland 11 wine Biological Station at Millport in August 1908, we had occasion to examine a few of the commoner Crustaceans and Molluses. One object in doing so was to obtain a general idea of the larval Trematode forms to be met with in the Clyde area, and in particular to investigate the occurrence of cercarix in the common edible and green crabs. The time at our disposal was not sufficient to permit of much material being examined, so that the number of larval forms to be described is small, but in the case of the crabs our efforts were more successful.

In addition to Cancer pagurus and Carcinus menas, a few specimens were examined of each of Eupagurus bernhardus, Portunus depurator, C'rangon vulyaris, Balanus balanoides, Venus cassina, Mytilus edulis, Aporrhais pes-pelecani, Patella vulgata, and Lima hians. Only the last-mentioned harboured cercarise. A few young fish, e.g. plaice, dabs, and bullheads, were also examined and in two of these encysted cercarice were found.

[^39]
## Cercaria excellens, nov.

This was found encysted in large numbers in Curcinus manas, and less frequently in C'ancer pagurus. It is undoubtedly the larva of some species of the genus Spelotrema, and, as will be shown later, the adult species to which it can most probably be referred is Sp. errellens, Nicoll.

Three out of every four green crabs were infected; in the case of the edible crab the infection was not more than one in five. At St. Andrews we lave found the infection somewhat greater ; every green crab examined there contained the cercaime in greater or less numbers, while about 25 per cent. of the edible crabs were infected. In the green crab the number of cercarize is frequently enormons, every organ and tissue in the crab's body being riddled with 'ysts, so much so that sometimes one would think that the mass of cysts was actually greater than the organ in which they are contained. The chief seat of infection is the liver and next to that the gonads, but no structure is immune, except the calcareous parts. The cysts are occasionally found throughout the muscles and along the course of the nerves, hlood-vessels, or alimentary canal. They may occur either singly or in clisters, hound to each other by the fibrous tissue in which they are embedded.

These ohervations agree with those of M'Intozh*, who forty years ago fomen the crabs at st. Andrews infected to the same extent with cercaria. Whether the cercariæ which he deacribed then are the same as those we have met with is a matter of donbt, but this will be referred to again later.

When extricated from their fibrous investment the cysts are seen to be globular in slape. In some cases they appear to be very slightly ovoid, but this is probally due to pressure in frecing them, and usually they can be made to assume the globular shape lyy suitable manipulation. At first we were inclined to believe that two different kinds of cysts were present, for many were olviously, even to the naked eye, much snaller than the others. Under the microscope the difference was further accentuated by the fact that the wall of the smaller cysts was proportionately much thinner than that of the large cysts. On more exhaustive examination, however, what may be interpreted as intermediate furms were discovered, midway in size between the large and small forms. In point of numbers the large eysts far exceeded the small and intermediate-sized cysts.

In a series of measurements of about 30 cysts, two-thirds

[^40]were found to have a diameter between 43 mm . and 49 mm . In these the thickness of the outer wall was $027-054 \mathrm{~mm}$., average 036 mm . ; and the thickness of the inner wall $\cdot 005-023 \mathrm{~mm}$., averag $\cdot 017 \mathrm{~mm}$. Thus the outer wall is two or three times as thick as the imer, but in one or $t w$, cases the ratio was not more than 3: 2. Only in a few cases was the cercaria expressel from the cyst in an undam ured condition. The approximate length of the cercaria was found to be $\cdot 8-1 \cdot 0 \mathrm{~mm}$. In every case the oral sucker was larger than the ventral, the dianeter being $0665-03 \mathrm{~mm}$. for the oral and $\cdot 06-065 \mathrm{~mm}$. for the ventral. In some cases the genital sucker was also measured and found to have an average diameter of 052 mm .

Of the remaining cysts a group of four measured $\cdot 36$ $\cdot 39 \mathrm{~mm}$, average 37 mm . In these the outer wall had a mean thickness of 015 mm . and the inner $\cdot 0(0) \mathrm{mm}$. In only one case was the cercaria obtained in an undanared state and its length was 7 mm . No difference in size could be detected between the oral and ventral suckers, each measuring $05 t \mathrm{~mm}$., while the genital body measured -048 mm.

A third group of five much smaller cysts measured $\cdot 27-$ $\cdot 32 \mathrm{~mm}$., average $\cdot 305 \mathrm{~mm}$. The outer and inner walls were -011 mm. and 007 mm , thick respectively. None of the cercarie from these were examined. From these figures there seems no reason to suppose that these groups are other than stages in the growth of the same cyst, and such being the case it is evident that the cercariæe increase considerably in size during their sojourn in the crab. The only alternative is that they represent the larva of three different adult species. It is unfortunate that more detailed examination of the smaller cercatiæ was found impossible, as that might have been of help in deciding the matter.

A fourth variety of cyst was met with, but only on one or two occasions. It was about the same size as the foregoing, but differed in having a cell-wall composed of only one very thin ( $\cdot 002 \mathrm{~mm}$.) layer. In none of these was the cercaria examined. 'They must apparently belong to a distinct species, unless, indeed, they are abnormalities. A possibility which might be suggested is that they are just some of the ordinary cysts in which the outer layer has been accidentally stripped off; but there was no evidence of this and in addition the thickness of the wall is much less than that of the immer layer even in the smallest of the cysts.

A detailed description of the anatomy of the cercaria is not necessary here, as it agrees well with that of the alult,
due allowance being made for the stage of cievelopment. The dimensions of the chisef organs have alrealy been given. The ventral surker is situated at the begiming of the posterior third of the borly length. The genital sucker lies close to its left side. The intestinal diverticula terminate at the level of the centre of the ventral sucker. The testes lie close behind that sucker, one on each sile, but the rolkglands are unt visible. In most cases the ovary can be male out on the right side of the ventral sucker, and in some the vesicula seminalis in front of the sucker.

As alreally mentioned, this cercaria is probably the larva of a Spetotromn species. The onle other genus which might come into question is Levinseniella, hut the character of the genital sucker points rather to Splotrema. ()f the species of the latter genus the only one which can le considered is Spel. exreflens, Nicoll, the large size of the cercaria exchuling the posilisility of its identification with any of the other species of the genus.

The adult sipelotrema errellens is found in great abundance in the herring-gull (Larus argentutns), both at St. Andrews and Mill purt. Syelutremu simile, Jiigersk., the next largest Spelotrema species, is much rarer.

W'ith regard to the cercaria described by M'Intosh \%, it is unformate that he gives no exact measurments either of the eysts or of the cercaria. By measurement of his fis ores (ph. viii.), which are magnified 180 diameters, we find that the erat in fig. 1 had a diameter of 14 mm , and that in fig. $2, \cdot 17 \mathrm{~mm}$. The cercaria in fig. 5 is exactly $\cdot 5 \mathrm{~mm}$. Loner. It requires but a glance at the plate to see that the cercaria in fig. 5 is much too large to have come from a cyst of the size shown in figs. 1 and 2. By the kindness of Profes:or II'Intosh a tube containing some of lis original material from Curcinus meruas was placed at our disposal, hut in it only one cyst was found. The diameter of this was 29 mm . ; the onter radially-striated wall was 01 mm . thick and the imer concentrically striated $\cdot 012 \mathrm{~mm}$. From these somewhat meagre details we are forced to the conclusion that Professor II'Intosh also had a variety of cysts under his observation, some of which correspond in size with those which we have found, but others being much sma!ler. The only other explanation is that some error has crept into his estimation of the magnification. It is hardly to be believed that the character of the infection of the crabs at St. Audrews has undergone a change from small cysts to large ones during the space of forty years.

A point of interest is that M'Tntosh apparently met with some of the single-walled cysts already referred to, for he says ( 1.202 ) that the wall of the cysts "consists of two layers marked by minute strix and specks; but the outer cannot always be seen."

Reference may here be made to Miss Lehour's investigations* of larval Trematodes in Carcinus mouas from the Northumberland coast. Her results appear to differ entirely from ours, for although she found the crabs fairly well infecterl, the cysts were of quite a different character, being singlewalled and oval. The cercariz in these cysts are apparently of the Spelotrema type. 'Their identity is doubtful, but it scems certain, at least, that they are not the same as tho cercarie we have just described. Miss Lebour, however, found a single specimen of another cyst in the crab. This was smaller than the others, spherical and double-walled. The cercaria was not examined, but from the size and character of the cyst it was presumed to be probably the same as M'fontosh had found. Whether this be the case or not it is carious that these double-walled cysts should be so rare in the Northmberland crabs in contrast to their great abundance at Sit. Andrews. It may possibly be regarded as an instance of the peculiar effect which local conditions may exert even on the parasitic fauna.

It may not be out of place to mention here another cercaria found by Miss Lebour $\dagger$ in Balamus balanoides and referred with much dunbt to Spelotrema excellens as the adult. The size ( 1 mm .) of the cercaria is suggestive of Spel. cutcellens, but the contiguration of the alimentary canal differs considerably from that in Spel. eaccellens and bears much more resemblance to that of Levinsemiella bruchysoma (Crepl.).

## Cercaria lima, nov.

Five specimens of Lima hians were examined and in two of them a single cyst was found. In both cases it was loosely attached to the imner side of the mantle-edge, projecting into the mantle-cavity.
'The cysts are spherical, about 3 mm . in diameter and have a thin, opaque, membranous wall. The liberated cencaria is $\cdot 6 \mathrm{~mm}$. long and of somewhat elongated oval ontline. It is colourless and very transparent, so that little of its internal anatomy could be made out. The suckers are both globular,

[^41]the oral having a diameter of $\cdot 120 \mathrm{~mm}$. and the ventral -152 mm .; the latter is situated at the beginning of the posterior third of the body. The cuticle is smooth and without spines. Just behind the ventral sucker two small nval testes are placed, one on each side, with their long axes directed ubliquely outwards and forwards. The ovary could

Cercaria lima.
not be distinguished, being prohably concealed hy the rentral sucker. A shont exchetory vesicle lies at the posterior end of the body. There is a small pharrix contiguous with the onal sucler; two simple intestinal diverticula arise immediately behind the fharynx and appear to terminate near the testes.

This is apparently the first record of this cercaria, and no other entozoa have hitherto been described from Lima hians.

Even with the scanty details given above, it is not difficult to recognize in this cercaria the larva of a species belonging to one or other of the genesa Steringothorus or Fellodistomum. The position of the suckers, their large size and particularly the prominence of the ventral sucker, the situation of the testes, and the smooth condition of the cuticle all support such an identification. The characters of the excretory vesicle and the alimentary system are also of importance. Moreover, these are the only two genera of British Trematodes with which the cercaria shows any affinity. More detailed differentiation seems at present out of the question. The small excretery vesicle without conspichous lateral stems and
the absence of œsophagus (although this may be due to contraction) are strong evidences in favour of Fellodistomum fellis (Olss.) being the adult; the only contra-indication to which is the fact that Anarrhichas lupus, the only known host of Fellodistomum fellis, is not common in the neighbourhood of Millport.

## Cercaria concava, nov.

In a young plaice (Pleuronectes platessa), about $4 \frac{1}{2}$ inches long, a small round cyst was found embed led under the skin. Its diameter was 17 mm . and it was very thin-walled, so that the cercaria was easily liberated. Its resemblance to Crryptocotyle concava (Cirepl.) is even at first sight very striking. The shape is flattened, considerably broader towards the posterior end than towards the anterior end. The leugth is $\cdot 45 \mathrm{~mm}$. and the breadth at the widest part $\cdot 22 \mathrm{~mm}$. 'The

Fig. 2.

Cercaria concava.
small round oral sucker has a diameter of 06 mm ., the prepharynx is 003 mm . long, the pharynx 04 mm ., and the œsophagus 04 mm . The diverticula have the shape characteristic of the adult Cryptocotyle, bending in towards the middle line in the vicinity of the genital sucker, then curving out, and finally turning in at their termination to approach each other. The excretory vesicle is clearly seen and consists of two fairly straight lateral tubes, begimning near the prepharynx and rumning into a simple, rather wide terminal sac at the posterior end of the body. The genital sucker is quite distinct, situated about the middle of the body. That this structure is not a ventral sucker in the true sense
of the term is evidenced l,y the fact that although the aperture is sharply enough defined, the sucker itself does not have the well-marked outline usually associated with the ventral sucker. Furthermore, the vestigial ventral sucker can be made out a little in front of the genital aperture, but its apenture is concealed in the genital sucker. Traces of two small testes can be detected in front of the ends of the intestinal diverticula, but none of the other organs are visible. The cuticle, as in the adult, is set with numerous regular scale-like spines.

This larval form appears to have hitherto escaped olservation. Its illentification as the cercaria of ciyptocotyle concava (Crepl.) seems quite justifiable without further proof, for it possesses the charactess of that species in a marked degree and there is no other british species with which it is likely to be confused. We have found, tuo, that Phulacrocorax !roculus (the shag), which is one of the hosts of the adult parasite (so) far, the only British host), feeds largely on small plaice, dabs, and flounders.

## Stephanochasmus baccutus, Nicoll. (Cercaria.)

We have to record this larva from Plruronectes limondi. Only one cyst was obtained, lut no special search was made for nowe ; its frequent occurrence in woung Plemonectids has already been failly well estallished. The eyst was embedded under the skin and its wall was very thin and membranous, the thick outer covering, mentioned ly Miss Lebour*, having prohably heen removed in freeing the eyst from the tissues of its linst. Its diameter was about 7 mm ., but it was more or less ovoid, according to the movements of the enclosed cercaria.

The length of the cercaria is $1 \cdot 8-2 \cdot 0 \mathrm{~mm}$. and in structure it agrecs very well with the adult Slephanochasmus baccatus. Anteniorly it is covered with numerous regularly arranged spines, which disappear a shont distance behind the ventral sucker. 'The oral sucker is encircled by two rows of larger and stouter spines which are closely applied to the aperture. They number 28 in each row and are regularly and symmetrically amanged, no gap being left in either of the rows. 'I hose of the anterior row measure 036 mm . in length, in the posterior row 04 mm . on an average. There is slight variation in length.

The oral sucker is terminal and measures 186 mm , in diameter; the ventral sucker lies near the middle of the

[^42]body and measures $19 \pm \mathrm{mm}$. The suckers are thus nearly equal, although in the adult the ventral sucker is considerably larger than the oral sucker. The grater relative increase of the ventral sucker, however, is of almost invariable occurrence amongst Distomids.
'The internal anatomy conforms very well to the Stephanochasmus type. The pear-shaped pharynx measures $14 \times$ -09 mm. ; the prepharynx is twice as long and the œeophagus half as long. The excretory vesicle, as commonly occurs in encysted cercaria, is of disproportionately large size. The testes are rather near the posterior end and the ovary is a little in front of them. The cirrus-pouch is well formed and extends to midway between the ventral sucker and the ovary. The yolk-glands were not very distinct.

The identification of larval Stephanochasmus species would appear to rest very largely on the number and relative length of the cephalic spines. Other features which aid in identifying adult species, such as the size of the suckers, the length of the cirrus-pouch, and the extent of the yolk-glands, are of very doubtful value in the case of cercarix. The yolkglands are not, as a rule, conspicuous enough, while the great increase in the length of the post-acetabular relatively to the pre-acetabular region as the genital glands develop and the cercaria attains maturity renders futile any differentiation based on the comparative sizes of the suckers or the proportionate length of the cirrus-pouch. Assuming, however, that the number of cephalic spines is constant, or very nearly so, in each species, it is obvious that this would provide a fairly reliable test in diagnosing species, except such as possess a nearly equal number of spines.

Of the known species of Sttphanochasmus, St. cesticillus (Molin), St. bicoronatus (Stos..), St. pristis (Deslongch.), St. minutus, Lss., and st. thombispinosus, Lebour, have all less than 40 cephalic spines. In st. caducus, Lss., there are 48, in St. trigle, Lebour, about $50(?)$, and in St. buccatus, Nicoll, 56. It seems hardly likely that the cercariæ of Si. caducus and st. buccatus could be confused, for not only is there a difference of 8 spines, but the anterior row contains the longer spines in S't. caducus, while the reverse is the case in St. baccatus. At the same time it must not be forgotten that it is often a matter of great difficulty to determine the length of the spines accurately, for owing to the curvature of the surface on which they are set they are usually seen somewhat foreshortened, and this applies more particularly to the spines of the anterior row. Between St. triglee and St. baccatus there is sreater difficulty in
deciding. In Miss Lebour's description * of St. trighte the number of spines is given as lying between 42 and 56, and the spines of the anterior row are slightly longer than those of the posterior row. From a specimen of what is apparently St. trigle oltained at St. Andrews in Coftus scorpius we find that the number of spines is 50 and that the posterior spines are slightly longer than the anterior. In this specimen it was noticed that the spines of the posterior now had a tendency to diverge symmotically from the middle line instead of being directed straight backwards, as is usually the case, but this may have been merely accidental. If the number 50 is confirmed for St. trighte it will robviously be easier to differentiate its cercaria from that of S't. buccutus than from that of St. caducus.

The occurrence of Strphanochasmus cercaria enessted in various Pleuronectid fishes has already been described by Johnstone $\dagger$ from Pleuronectes limauda (recorled as Distomum valdeinfletum, Stoss.) and Miss Lehour $\ddagger$ from $P l$. limanda, Pl. microcephalus, Pl. cynoglossus, and Drepanojesetta pilatessoides. As Johnstone makes no mention of the number or size of the cephalic spines it is impossible to be sure about the identity of the cercaria which he found. In Miss Lebour's specimens the number of spines varied from 48 to 58. From these ouservations two alternative conclusions may be drawn, either that the number of spmes may vary within such wide limits in the same species or that Miss Lebour's collection included cercarix belonging to more than one species. The former is opposed to most observed facts ; the latter seems much more likely. It is not at all improbable that the cercarie of St. caducus, St. trigla, and St. baccutus are all to be found encysted in young Pleuronectid fishes.

## XXVIII.-Nero Species of Dendromus and Tatera. By R. C. Wroughton.

In a small collection of mammals made by Dr. Jameson in the Transvaal I found some specimens of a Dendromus which seems to require a new name ; and, further, in comparing

[^43]these specimens with those in the Natural History Maseum, it became evident that two Nyasan forms also require names.

## Dendromus jamesoni, sp. n.

A small Dendiomus of the pumilio group, but with a wellmarked dorsal stripe.

F'ur soft and close, length $8-10 \mathrm{~mm}$. On back. (ieneral colour as in $D$. pumilio, but a strongly marked, black dorsal stripe.

Dimensions of the type:-
Head and body 60 mm . ; tail 78 ; hind foot 16 ; ear 13.
Skull: greatest length 20.5 ; basilar length 15 ; zygomatic hreadth 11; brain-case breadth 10 ; nasals length $7 \cdot 2$; diastema 5 ; upper molar series $3 \cdot 1$.

Hab. Zoutpansberg, 'Transvaal.
Typue. Adult female. B.M. no. 9. 1. 20. 27. Original number 135. Collected 6th July, 1907, by Dr. H. L. Jameson.

Seven specimens examined.

## Dendromus whytei, sp. n.

A small I)endromus of the pumitio group, rather smaller and slighter than either pumilio or jumesoni, with an obsolescent dorsal stiipe.

Colour above as in pumilio and jamesoni, but the dorsal stripe of the latter obsolescent or absent. Under surface white, but usually much suffused with ochraceous. Ears small.

Skull more delicately formed, narrower across the palate than in jamesoni.

Dimensions of the type :-
Head and body (c.) 60 mm . ; tail (c.) 85 ; hind foot 17 ; ear 11.

Skull: greatest length 20 ; basilar length 15 ; zygomatic breadth 11; brain-case breadth $10 \cdot 5$; nasals length 8 ; diastema 5 ; upper molar series $3 \cdot 1$.

Hab. Nyasa (type from Fort Hill).
Type. Old male. B.31. no. 97. 10. 1. 131. Original number H. J. 117. Collected by Mr. A. Whyte, and presented to the Natural History Museum by Sir H. H. Johnston, K.C.B.

Twelve specimens examined, from Nyika Plateau, Zomba, and Mt. Malosa ; in almost all there is a perceptible darkening along the mid-dorsum, but in only one is there an appreciable black stripe.

The known members of this pmilio group may be arranged in a key as follows:-
A. A well-marked dorsal stripe. (Transvaal.). . jamesoni, sp. n.
B. Dorsal stripe absent or obsolescent.
a. Dorsal stripe obsolescent. Ear=11 mm.
(Nyasa.)
whytei, sp. n.
b. Dorsal stripe absent.
$a^{2}$. Size smaller. Skull 18.5 mm . Ear $=$
10 mm . (Angola.) ................. ansorgei, Thos. \& Wr.
$b^{1}$. Size larger. Skull $20-21 \mathrm{~mm}$.
$a^{2}$. Ears large, 15 mm . Colour paler.
(Cape Peninsula.) ..................
$b^{2}$. Ears smaller, 12 mm . Colour darker.
(Cameroons.) ...................... . messorius, Thos.

## Dendromus myike, sp. n.

A Dendromus of the D. mesomelus type, with a claw on the fifth toe. Rather smaller than that species, with a proportionally much shorter tail and smaller ears.

Size rather smaller than $D$. mesomens. Fiur rather shont ( $9-10 \mathrm{~mm}$. on back). Colour near to "fawn colnur" abone, pure white below; dorsal stripe well-marked from the shoulders backwards. Hands and feet white. Ears small; tail short as compared with Mesomelas.

Dimensions :-
Head and body (c.) 70 mm. ; tail (c.) 8.5 ; hind foot 18 ; ear 12 .

Skull: greatest length 23 ; hasilar length 17 ; zygomatic breadth 12: brain-case breadth $10 \cdot 1$; masals length $8 \cdot 8$; diastema $5 \cdot 5$; upper molar series $3 \cdot 6$.

Hab. Nyika Plateau, British Central Africa.
Type. Adult female. B.入I. no. 97. 10. 1. 123. Original number H. J. 7. Collected by Mr. A. Whyte in June 1s9ti, and presented, with four others besides spirit-specimens, to the Natural History Museum by Sir H. H. Johnston.

The short tail, small ears, and the bluish or drab tint in its colouring suffice to distinguish this species easily from D. mesomelas, and, à fortiori, from D. insignis.

It is curious that two of the series of five specimens taken at the same time and place, and not otherwise differing in any way, have the bases of the hairs of the belly of a dark slate-colour, while in the type and the other two specimens the corresponding hairs are white to their bases.

Unfortunately no measurements were recorded by Mr. Whyte, and I have been obliged to base those given above on a spirit-specimen taken at the same time and place.

The following is a key to the known species of the mesomelus group. 1 exclude pullidus, Heuglin, and mysticu'is, Heuglim, from Somaliland, about which information is not available, even as to whether they should be classed with $D$. mesomelas or $D$. melanotis.
A. Size rather larger, hind foot $=21-22 \mathrm{~mm}$.;
ear larger, $=15 \mathrm{~mm}$. Dorsal stripe very
strongly marked. (British East Africia.) . D. insignis, Thos.
B. Size smaller, hind foot $18-20 \mathrm{~mm}$.
(c. Ear larger, 15 mm ; tail longer, 100-105 mm. (Cape to Natal.) ................. D. mesomeles, Brants.
b. Ear smaller, 12 mm ; tail shorter, 8:5-90 mm. (N. Nyasa.) . . . . . . . . . . . . . . . . . D. nyike, sp. n.

## Tatera smithi, sp.n.

A Tatera closely resembling T. liodon in proportions and colouring, but differing in its long posterior palatal furanima and extraordinarily broad brain-case.

Dimensions of the type :-
Head and body 155 mm . ; tail 145 ; hind fort 34.5 ; ear 20.

Skull: greatest length 42 (c.) ; basilar length 345 ; interorbital breadth $7 \cdot 4$; brain-case breadth $18 \cdot 6$; anterior palatal foramina $8 \cdot 2$; posterior palatal foramina $3 \cdot 6$; diastema 12 ; upper molar series 6.8.

Hab. Mubende, Unyoro.
Type. Old female. B.M. no. 7. 10. 1. 14. Original number 34. Collected and presented to the National Collection by Mr. L. M. Seth-Smith, 23rd March, 1908. 'Two specimens.
T. smithi, while closely resembling in general facies $T$. lioclon from Lake Mweru, has the long posterior palatal foramina so characteristic of the northern forms from Egypt and Somali.
XXIX.-Notes on the Forficularia. - XV. The Esphalmeninæ. By Malcolay Burr, B.A., F'E.S., F.L.s.', F.Z.S., \&c.

In 1901 Verhoeff (SB. Ges. naturf. Fr. no. 1, p. 7) formed the family (konolabidx, the essential character being the form of the prosternum, which is strongly narrowed posteriorly.

The second important feature is that the pygidium is fusel with the last dorsal segment.

Now the latter character is not peculiar to this group ; it marks also the following genera:-P!yratra, Erkinopsatis, Echinosoma, Forcipulu, Allostetlues, Latidura, Psalis, Latidarodes, Carcinophora, Anisolubis, and the six gemera of the Brachylabina referred to in these pares ('Annals,' vol. ii. p. 247, 1908). It is, in fact, the distinguishing feature of the family Labiduride, which includes all the genera mentione above, and falls naturally into several suffamilies.

In an earlier note on the Gonolabide ( $\mathrm{I} r$. Ent. Sos. London, 1904, p. 293) I have pointed out that this narrowins of the prosternum oc:urs in ( $\dot{x}$. primmusyi, $G$. silvestrii, G. lativentris, but not in (r. Kirlyi nor in (i. jacena; consequently, by his characterization of the Gomolabide, Verheeff excludes the latter species. This is unfortumate, because when I erected the gemus (ronolalis (Ann. S'e. Ent. B:1s. xliv. p. $4 \mathrm{~s}, 190(0)$, I specially mentioned $G$. jucence as the type of this genus.

Verhoff was evidently unfamiliar with the literature of the subject, relying almost, if not quite, entirely on de Bormans's monograph. Consequently he falls into the curious error of quoting (l. c. p. 7) "(ionolubis (Burv) et miki," anl on the next pare "Typus: (f. lativentris Phul." We must now separate "Cronolatis Bure" from "Comolulis mili""; the former has a parallel prosternum and the type is $G$. jurana, the latter has a narrow prosternum and the type is $G$. lativentirs.

A new name is required for "Gonolur is milh," fur which I propose Esphalmenus*, with G. Lativentris as type.

The Gunolabids of Verhoeft', therefore, does not include the genus Gonolubis, and must be replaced by the name Esphalmenina, reducing the rank to that of a subfamily. There is a second genus in this subfamily, namely Gonolabina, Verh. Like most of that author's names, there is a lack of originality in it ; this is more unfortunate since this genus really belongs to the Esphalmeninx, and has no commexion with Gonol his, which genus does not require a separate subfamily, but falls into the Anisolabinæ.

## Subfamily Esphaluentite, nov.

Gonolabide, Verhneff, SB. Ges. naturf. Fr. no. 1, p. 7 (1901); Burr, Tr. Ent. Soc. London, p. 293 (1904).
Apter us ; antennæ, feet, and pygidium as in Labiduridæ generally ; prosternum strongly narrowed posteriorly.

[^44]
## Table of Genera.

## I. Esphalmenus, gen. nov.

Anisolathe, Bormans, Ann. Soc. Ent. Bule. xrvii. ii. p. 62 (I× 3 ) ; id. Tierreich, Forf. p. 51 (1900) ; id. Ann. Mus. Civ. Gen. ii. p. 4 ǒl (1906).

Gonolatis, Burr, Ann. Sic. Ent. Beler. xliv. p. 12 (1900); Verhoeff, sB. Ges, naturf. Fr. p. 7 (1901) ; Kirby, Borelli.
Antenne multo-segmentate; corpus apterum ; pronotum quadratum: abdomen ot depressum, basi angustum, usque ad appicem fortiter dilatatum; of suhparallelum; segmentum ultimum dorsale of latum, transversum, $f$ angustum; margine postico recto, integro, abrupte et angulatim prgidio verticali separatum: forcipis bracchia of ralida, basi valde remota, fortiter arcuatd; ㅇ recta, simplicia.
Entirely apterous.
Antenne withrumerous (?30) serments, cylindrical ; third long ; fourth, filth, and sixth much shorter, the remainder gradually lengthening.

Head smooth. Pronotum rectangular.
Abdomen of depressed, narrow at the base, then strongly dilated towards the apex, which is several times wider than the base ; in of parallel and less depressed.

Last dorsal segment very hroad, posterior margin straight ; in of narrow and sloping.

Pygidium of vertical, fused with dorsal segment, but the junction manked by a sharp angle, almost acute, as in all typical Labiduridæ: pygidium of narrow.

Forceps with the branches $\delta$ stout, very remote at the base, triquetre, tapering and strungly arcuate. In of straight, tapering, and subcontiguous.

Type of the genus: Forficula lativentris, Philippi, Z. Naturw. xxi, p. 47 (1863).

## Table of Species.

1. Forcipis bracchia of prope basin superne cristata : species africana....................
2. peringueyi, Borm.
1.1. Forceps superne inermis: species Americe meridionalis.

## 1. Esphalmenus peringueyi, Borm.

Cionolubis perinyueyi, Bmm. Am, Mas. Civ, (ion. xx. p. 4.51 (1900); Burr. Tr. Ent. Sue. Lon Lon, p. E!3(1901) : Kirby, Cat. Orth. i. p. 16 (1904).

South Af:ica: Capre (inlony, Cale lon (Borm., coll. Brunner, and c. m.), taken by Peringuey.

De Bormans only gave a very brief description of this species, but ample for its ilentification. It is the only 01.1Word member of the semus, and the ablomen being for or five times as wide at the apex as at the base, its appearance is very distinctive; the general colour is brick-rel. The dimensions are as follows:-

|  | $\mathrm{c}$ | $\underset{\text { min. }}{\substack{\text { P. } \\ \hline}}$ |
| :---: | :---: | :---: |
| Lencth of bedr | 10:5-11\% | 11 |
| Breadth of pronotum | 1.5-1.75 | 175 |
| Breadth of base of abdomen | $1 \cdot 75-2$ |  |
| Breadth of apex of abdomen | 3-5 | 3.5 |
| Length of forceps. . . . | 2 | 2.5 |
| Breadth of forceps | $2.5-4.75$ | 1.5 |

## 2. Esphalmenus camposi, Borelli.

Gomulubis campasi, Borelli, Bull. Mus, Tor, xxii. n. $5.52\left(1.900^{-}\right)$.
Ecuador.
This species is carefully described hy Borelli, who gives a figure of the characteristic form of the ventral surface of the apex of the abdomen.

It differs from its congeners in its shining black colour and less strongly dilated abdomen.

## 3. Esphalmenus silvestrii, Borelli.

Gonalahis silrestrii, Pimplli, Boll. Mus Tor. xrii. mo. 418, p. 4 , fig. (1902) ; Burr, Bull. Mus. H. N. Paris, p. 31 (1908).

Gonolabis sylvestrii, Kirby, Cat. Orth. i. p. 31 (1904).

## Patagonia.

This species is well described and figured by Borelli.

## 4. Esphalmenus lativentris, Phil.

Forpleula lutiventris, Philippi, Zeitschr. ges. Naturw. xxi. p. 217 (1863). Anisolubislativentris, Borm. Ann. Soc. Ent. Belg. xxvii. p. 62, pl. ii. fig. 3 (1883) ; id. Tierreich, Forf. p. 51 (1904).
Gonolabis lativentris, Burr, Amn. Soc. Ent. Belg. xliv. p. 49 (1002); id. Tr. Ent. Soc. London, p. 293 (1901) ; id. Bull. Mus. II. N. Paris, p. 31 (1908) ; Borm. Ann. Mus. Civ. Gen. XXX.-Notes on the Forficularia.-XVI. On Dermaptera in the Greifsucald Museum, with Synonymic Notes on some of Gerstacker's Species. By Malcolm Burr, B.A., F.E.S., F.L.S., F.Z.S., \&c.

As the identity of four species of Dermaptera described by Gerstæcker from West Africa has long been a puzzle, I am very glad to have the opportunity of putting all doubts at rest. Dr. Muller, Director of the Greifswald Muscum, has very kindly communicated me the types of Gerstrecker, together with some material from various sources; this is worked out in the following short paper, in which the synonymy of the four doubtful species is established, as also of a species of Proreus.

I avail myself of the opportunity of once more expressing. my gratitude to Dr. Muller.

> Apachys chartaceus, Haan.

Soekaranda (Dohrn), 1 ㅇ․

> Diplatys cf. nigriceps, Kirby.

Java orient (Fruhstorfer).
This specimen is undeterminable, because imperfect.
Diplatys vosseleri, Burr.
Nguëlo, East Africa (Rolle), 1 ठ.
Cylindrogaster gracilis, Stål.
Theresopolis (Fruhstorfer), 3 б̃, 1 ㅎ. Ann. \& Mag. N. Hist. Ser. 8. Vol. iii.

## Dicrana, sp. n.

S.W. Java, Palabuan (Fruhistorfer), 1 i.

Allied to I). horsfieldi and 11. quadrigutula, but differs entirely in colour.

The pronotum is tawny, with a black $\mathbf{V}$, whereas it is rel in $I$. quedriguttuta and dark with a pale berner in $I$ ). hurisfildi; the pronctum is dark in the latter, red in the former species, but tawny in this. In I). harsstieldi the elytra are yellow ish ; in D.qumedriguttate back, with four reldidh ap, ts ; in this species all black.

The promotum is rectangular, the pemultinate ventral segment of the d has a median sulcus in K. horstibldi an! I). quadriguthatu. It is not advisable to give a name and as tormal descifition to this apecies without the male.

## Echinosoma wahllbergi, Dohrn.

Nguëlo, East Africa (Rolle), 1 ot.

## Pyragra brunnea, sp. n.

Statura minore : celore rufio, pronoto, alis pelibueque fulvo-signatis ; elytris fuscis.

|  | $\delta^{\circ}$. | 오. |
| :---: | :---: | :---: |
| Long. corporis | 10 mm . | 10 |
| , forcipis | 1.5 | 1.75 |

Size relatively small.
General colour brown.
Antem.a with about thirty segments : first not very long, stont and clavate; scernd short, eylimdrical; third eylimdical and long, quite four times as long as broad; fourth and tith quite short, almo-t globular, about as hroad as long; sixth, seventh, eighth, and ninth dr. gradually lengthening, very eently clubbed at the apex, the apical ten segments slender, almost cylindrical ; in colour dull brown.

Head broal, black, mouth-parts tawny; tumid and bristly.
Ironotum transverse, convex anteriorly, straight posteriorly, the angles rounded and sides gently rounded; blackish brown, with a tawny spot on each side.

Elytia dull brown, rough, cluthed with short bristles.
W゙ings dull brown, pale rellowish alng the suture.
Feet tawny, femora and tibia banded with fuecous.
Abdomen depressed, parallel, deep reddish brown, rugulose and bristly.

Last dorsal segment transverse in both sexes, ample, posterior margin straight ; on each sile there is a longitudinal ridge which runs into the posterior margin at the angles, which are rounded.

P'enultimate ventral segment of transverse, with a shallow, median, round emargination and each lobe broadly roundel ; in o not emarginate, obtuse-angular.

Forceps with the branches remote in $\delta$ at base, stout, triquetre, tapering arcuate, straight, contiguous, triquetre, and serrate.
Peru: Fonteboa (Ilamel, ô, in MLus. Greifswald) ; Iguapo ( $q$ in c. m., et coll. Gadeau de Kerville).
This species approaches nearest to $P$. puraguayensis, Bor., but is smaller and differs in pattern. It can hardly be confused with the other species, if only on account of its much smaller size.

## Anisolabis, ? sp. n.

Victoria (West Africa).
There are six specimens of Anisolubis from Victoria. I dare not offer an opinion on them ; probahly some at least are immature specimens of $P_{\text {sislis. }}$. One adult appears to bas allied to A. compressa, Borelli, but is less compressel, and the antemme and feet are somewhat differently coloured.

## Anisolabis maritima, Borm.

N. 17, 481. Probably referable to this species.

## Brachylubis nigra, Scudd.

## Fonteboa (Haknel), 1 q.

## Psalis cincticollis, Gerst.

This specimen is Gerstæecer's trpe. It is, unfortunately, a female, but it is evidently a Psalis. It is larger than $r$. picina, Kirby, the other West-African species, and is probably quite distinct. In the short elytra and pronotum it approaches to $P$. delifis, Burr (East Africa) ; in the yellowish basal segments of the antemme it agrees with both; in the relatively long fourth antemal segment it approaches l'. picina. It is to be hoped that the male will be discovered soon, so that its true relations may be determined.

> Long. corporis
> $17 . \overline{\mathrm{mm}}$.

> 3

## Spongiphora quadrimaculata, Stål.

Aburi, 2 ठ.
These are Gerstæcker's original specimens of For firula protensa, which is consequently sumk as a symonym. 'There is no doubt whatever as to their identity.

Spongiphora croceipennis, Serv.
Brazil, San Paul (Staudinger), 1 ठ'.
Platylabia sparattoides, Borm.
Java orient. (Frulestorfer), 3 ठ, 2 q, and nymph.
Mecomera brunnea, Serv.
Fonteboa (Hahnel), 1 ot.
Chresospania pederina, Gerst.
Bonjongo, Aburi (Buchh.), 2 q.
These, ori, inals of (rerstecker, are identical with Ch. hongiana, Borg, and C'\% escalerr, Burr, which emsequently fall as synonyms.

Sphingolabis semifulva, Borm.
Java orieut. (Fruhstorfer), 1 ठ.

## ? Labia sicaria, Burr.

Java orient. (Fruhstorfer), 1 of probably identical.

## Proreus elegans, Borm.

Java orient. (Fruhstorfer), 1 ठ, 1 ㅎ.
Thanks to the kinduess of Dr. Gestro, I have been able to compare these specimens with de Bormans's type, and there is no doubt as to their identity ; the female is obviously identical with the specimen in the Budapest Museun described by me under the name of Apterygida lingua (Termes. Fiuz. xxv. p. 486, pl. xx. fig. 8,1902 ), well characterized l,y the tongue-shaped pygidium, and the specimen doubtfully referred to as a variety of Ch. eleggans (I.c. p. 4S5) is the male. It differs from the other species of Proreus in the relatively broad pronotum, agreeing thus with the $P$. sobrius, Borm., which resembles $P$. elegans in build and structure, but differs in colour and in the form of the occiput, which is tumid ons
each side, whereas the whole head is smooth and gloluse in $P$. elegans.

## Elaunon erythrocephalus, Oliv.

Abo: Simbareni (Bucch.), 2 б, 2 ㅇ.
I'hese are the original specimens of Chelisoches pulchellus of Gerstæcker, which must consequently be sunk as a synonym.

## Doru lineare, Esch.

Bahia (Fruhatorjer), 1 õ; Guatemala, 2 б, 1 q; Theresopolis (Fruhstorfer).

Var. californica, Dohrn.
Theresopolis (Fruhstorfer), 3 §, 1 \&.
As the synonymic results established in the foregnom paper are rather important, it is worth while repeating them :Brachylabis cincticollis, Gerst., in MIt. Ver. Vorpomm. xiv. p. $4 \pm$ (1883), is a trie Psalis; it is allied to Psalis picina of Kirby, and may prove to be identical when the male is discovered.

Forficula motensa, Gerst. (l.c. p. 45), is synonymons with Spongiphora quadrimaculata, Stål.
Forficula pecterina, Gerst. (1. c. p. 46), is identical with C'hetospanico bonyiana, Borg, and Ch. escalerce, Burr, so that the correct name is Cheetospania peederina (Gerst.).

Chelisoches pulchellus, Gerst. (1. c. p. 42), is synonymous with Elaunon erythrocephalus (Oliv.).
Apterygida lingua, Burr (Termes. Fïz. xxv. p. 486, pl. xx. fig. 8, 1902), is the female of Proreus elegans, Borm.

## XXXI.-On Mammals collected in Turkestan by Mr. Douglas Carruthers. By Oldfield Thomas.

'The British Museum has recently received a collection of mammals, obtained in different parts of 'Turkestan by Mr. Donglas Carruthers, one of the mammal collectors to whom the remarkable success of the recent Ruwenzori Expedition was due.

Mr. Carruthers spent the winter of 1907-8 at Samarkand and Boklama, making collections in the threezones accessible, from there-the desert, fertile, aml mountain reqions of 'Turkestan. Then in the smmor he marle an exension up to the Iissar Momitains, on the somth site of the Zaratishan Valley, 100 miles east of Samarkand, and afterwands to the Ak-sai Plateau, N. of Kashgar.

Although the recrion is fairly well known to Russian maturalists, the Brilish Aluacmun has hitherto heen very badly off for mammals from Trumestan ; and this serics is therefore of mud impontance to ns for eomparison with our growing collections of Perian and N. Imlian animals.

120 specimens ane emmomated, helonging to 23 species, of which four have meended description as new, berifus there others from adjacent pants of Central Asia, alrealy in the Muscum Collection.

## 1. Nyctalus noctula, Schr.

む. $76,77,78,79$; ㅇ․ 74, 75. Samarkand. $2000^{\prime}$.

## 2. Pipistrellus pipistrellus lacteus, 'Temm.

उ. 2, 3, 25 ; 우. 1. Samarkand. $2000^{\prime}$.
In describing his P'festrellus buctriumus* Dr. Satunin has not shown any reason why Mobsun's definite identification $\dagger$ of 'Temminck's luctens with the prale-coloned E. T'urkestan l'ipistrelle shath be ignored. Without evilence that the identification is wrong, the name should be used.

Mureover, Severizoft's lespuruyo ukekmuli, 'Lemm., var. almatens1s $\ddagger$, dating from $15 i \not \subset$, wonhe also appear to be the same form.

## 3. Erinaceus macracanthus, Blanf.

Both summer and winter pelages are represented in this series, but there is not the material difference between the two that occurs in the next species.

## 6. Spermophilopsis leptodactylus, Licht.

万. $30,92,94$; ㅇ. $55,60,63,64$. 50 miles S.W. of Bokhara. 600'.

Nos. 92 and 94, killed 20th May, are in the curious short summer pelage, though with a few hairs left of the soft winter coat.
"Shot on sand-hills."-D. C.

## [Arctomys littledalei, sp. n.

The orange-rufous marmot of the Pamirs, hitherto crreneously termed A. caudutus, Jacq. Desc:iption infootnote..]

## 7. Arctomys littledulei flavinus, subsp. n.

उ. 117 ; ㅇ. 118. Hissar Mts., 100 miles E. of Samarkand. $10,000^{\prime}$.

General characters of A. Tittedelei, but the body-colour faler throughout, more yellowish, the hairs brown at base,

* Allied to A. cundatus, but the back, instead of being broadly washed with black, wholly taway or ochraceuns tamme-the hairs blackish at base, their middle zone buffy or wehraceons buff, and their ends tawny, with miunte and inconspichous back tips. Under surface duller tawny: Cheeks and sides of neck little lighter than rest of body. Crown blackish, as is also a patch on the top of the nose. Hands and feet ochracenis tawny. Tail long, dull ochraceous tamny, with a prominent black end.

Skull decidedly smaller than that of the true A. caudatus.
Dimensions of the type (measured in skin) ;-
Head and body (probahly stretelred) 5x0 mm.; tail 240 ; hind foot 80 .
Sliull: upper length (6); basilar lometh $8: 3$; greatest breadth 61; nasals $37.5 \times 17.3$; length of upper tooth-series 22 .

Hab. Alai Mts., Pamir.
Type. Old female. B.M, no. 92. 1. 1. 7.
The British Musenm owes to Mr. St. (ieorge Littledale its first specimens of this splendid marmot, and has since received others from tho St. Petersburer and Warsaw Mu-eums. There have been hitherto considered as identical with A. coundatus, Jacq., but the slines of this latter receised from Col. Ward and Mr. Whitehead slow such constaner in their larger size and possession of a broadly black-washed back that it is erident that the Pamir species should be distinguished from them, and I have had much pleasure in maming it in honour of the well-hnown explorer who discovered it.
cream-buff for their middle zone, their ends tawny, withont black tips. Under surface between buffy and ochraceous thuff. Sides of neck and area round and over shoulders clear buffy, without tawny tips, this contrasting with the top of the neck, which is darkened by the tawny ends of the hairs. Heal brown, beoming grarlually tamy posteriorly. Hands and feet buff. Tail dull buffy or pinkish buff, the end scarcely darker.

Skull about as in true $A$. litlledalei.
Dimensions of the type (measuren in the flesh) :-
Head and body 470 mm .; tail 220 ; hind font 82 ; ear 28 .
Skull: upper length 9.5; basilar length 84; greatest breadth 57 ; length of nasals 39 ; length of upper toothrow 21.

Hab. as above.
Type. Alult female. Original number 118. Collected 20 th June, 1908.

This is probably the marmot called $A$. cemelatus by Severtzoff. It has, of course, nothing to do with that species, from which it is even further away than A. litledulec, of which I porisionally make it a subspecies. It is readily distinguished from the later by its paler gromed-colour, the prominent pale areas on the siles of the neck, and by the absence of a black tip to the tail.

An imperfect skin from Surk, N.W. Monsolia, presented to the Museum by Mr. H. J. Elwes, would also appear to be referable to this form.

## 8. Arctomys centralis, sp. n.

Avctomys dichrous, Büchner, nee Anderson.
J. 121 (immature). Ak-sai Plateau, 120 miles N. of Kashgar. 12,000'.

A small species of a colour intermediate between the brown marmots of the himaluyames group and the yellow ones of the caudutus-littledulei type. Fur of back for its basal two-fifths blackish brown, then two-fifths cream-buff, the terminal fith dark brown. Belly strongly contrasted dark rufous.

Dimensions of the type (measured in skin) :-
Head and body (stretched) 600 mm . ; tail 155.
Sisull: upper length 95 ; condylo-Lasal length 96 ; greatest breadth 62.5 ; masals $41 \times 16.3$; palatilar length 50 ; length of upper tooth-series 24 .

Hab. Tian-shan. Type from Mt. Boro-choro.
Type. Old male. B.AI. no. 92. 1. 1.5. Collected 15th

July, 1889. Receivel in exchange from the St. Petersburg Museum.

The small red-bellied marmot of the Tian-shan was identified by Dr. Biichner as A. dichrous, Anderson; but a cotype of this latter in the British Museum shows that it is a wholly different animal, of a more or less chocolate-brown colour. Dr. Büchner has so fully described the present species and stated its relationship to the other Siberian forms that further detail is not now required.

It may be noted that A. baibacinus, Branlt, is absolutely a nomen nudum, whether Dr. Büchner was or was not right in separating the present animal from it.

## 9. Rhombomys opimus, Licht.

б. $34,54,61$; ㅇ. $56,57,59,62,88,93.50$ miles S.W. of Bokhara. $600^{\prime}$.

## 10. Meriones tamaricinus, Pall.

$$
\text { ठ. 5, 98, } 99 \text {; ¢. 4, 95. Samarkand. } 2000^{\prime} \text {. }
$$

## 11. Meriones eversmanni, Bogd.

ठ. 23, 67, 84, 85; ㅇ.7,68, 71. 10-20 miles S. of Samarkand. $2000^{\prime}$.
"In small colonies on semi-cultivated desert."
I provisionally use the name eversmanni for this gerbil as being undoubtedly applicable to it, but it is so closely related to the Kandahar M. erythrourus, Gray, that its ultimate union with that species is very probable.

Gerbils of the same type are widely distributed over S.W. Asia, examples from Karyatein (Kargeten), near Damascus, being quite similar to typical Afghan specimens. Sundevall's M. crassus from Sinai also belongs here.

A smaller species, M. longifrons, Lat., occurs in S.W. Persia (Ahwaz, Busrah, \&e.) and Arabia (Jedda).

## 12. Meriones meridianus, Pall.

ठ․ $43,44,45,46,51,52$; ㅇ. $45,49,50.50$ miles S.W. of Bokhara. 600'.

Büchner has placed Blanford's cryptorhinus as a synonym of meridianus, but specimens of it in the British Museum indicate that, while undoubtedly closely allied, it may be distinguished by its larger size.

The specics described in the footnote * was also considered by Büchner as 11. meridianus.

13. Mus ratues, L.<br>o'. 20. Hills south of Samarkand. $4000^{\prime}$.

14. Mus wagneri, Eversm.

उ. $15,36,83,96$; ㅇ. $6,8,10,13,14,17,18$. Samarkand and southwards. 2000-3000'.

8. 112. Hissar Mte., 100 miles E. of Samarkanl. $9500^{\prime}$.

> * Meriones biichneri, sp. n.

Allied to .II. merifianus, but with murh shorter ears. (ieneral colonr
 darker and richer than the sandy colsur of $3 I$. moridiams. Cndur =urface pure white to the romt- of the hais. Fars very -homs, 11 man. instend of
 from the crown, their proectote bright buffy with white end. Hauds and feet white; sules of the latter wholly hairy exemp a -mall font umder the calcaneum ; claws white. Tail mifombly tatwe nehraceons abore and below, a few of the terminal hairs tipped with black.

Skull apparently quite as in M. meritumus, except that the bullie are rather smaller.

Dimensions of the type:-
Head and body (in slin) 11.5 mm ; ; tail (fin) 8.): hind fyot (wet) 27 ; ear (wet) 11.

Skull : greatest length 32.2: breadth on aulitory bullæ 18.
Hab. Deleun Mts., Dsungaria.
Type. Adult mate. B.Mi. no. 93. 1.1.11. Collected br N. Przeralski, October 18-t, and receired in exchange from the st. Petershurg Museum,

This gerbil was referred to M. moritinmes by Buchner, hut he camnot hare noticed the striking difference in the size of the ears. From " FierSillus" liozlovi, Satunin, it differs by its white claws an l untufted tail.

## 17. Microtus (Nicr.) ravidulus, Mill.

子3. 123,124 ; ㅇ. 120,122 . Ak-sai Platean, 120 miles N.E. of Kashgar. $11,000^{\prime}$.

Practically topotypical of Miller's species, which was described from Ok-chi, in the valley of the Ak-sai River, at $7500^{\prime}$ 。
18. Microtus (Pitymys) carruthersi, sp. n.
ó. 105, 108, 109, 110 : 우. 106, 107, 116. Hiscar Mits., 100 miles E . of Samarkand. $9000-10,000^{\prime}$.

Apparently allied to the European subgenus Pitymys, but with mamme and some dental resemblances to Phuiomys.

Size rather large for a Pitymys. Fur long, very soft and fine; hairs of back about 12 mm . in length. General colour above near " hroccoli-brown," but varying a good deal in the different specimens. Under surface dull whitish, the slaty lases of the hairs showing through. Ears fainly long, quite evident beyond the fur, pale brown. Itaads and feet dull whitish above ; claws rather longer than in ordinary Pitymus, lut not so long as in Fhutomys ; soles apparently with only five pads, their posterior part thickly hairy. Tail fairly long, more than twice the length of the hind foot, well but not heavily haired, brown along its middle line above and at the end, dull whitish on sides and below. Mamme $2-2=8$.

Skull lightly built, low, smooth, rounded, not ridged, its general shape not very unlike that of $M$. ( $P$.) majori, but the brain-case is shorter and the face more developed. Nasals very broad anteriorly, tapering behind. Palatal foramina, posterior palatal region, and bulle all about as in that species.

Tooth-pattern quite as in Phaiomys, as figured by Miller *, $m^{3}$ being similarly bilaterally symmetrical, thongh the middle section is even less constricted in the middle line. Below the anterior molar is quite like Niller's figure, except that there is usually a small extra external angle at the middle of the long anterior lobe, making five salient extermal angles to the tooth.

Dimensions of the type (measured in the flesh) :-
Head and body 101 mm . ; tail 39 ; hind foot 16 ; ear 13.
Skull: greatest length $2 \pm .5$; basilar length 22 ; zygomatic breadth 14 ; nasals $6.1 \times 3.6$; interorbital breadth $3 \cdot 7$; palatilar length 13.5 ; diastema $8 \cdot 3$; palatal foramina $4 \cdot 6$; upper molar series (crowns) 5.7.
$H a b$ as above.

$$
\text { * N. Am. Faun. no. 12, p. } 57 \text { (1896). }
$$

Type. Adult male. Original number 105. Collected 14th June, 1908.

I have been much puzzled as to where this peculiar little role should be placed. It differs from all the menbers of l'itymys hy its more numerous mamma, and in this respect, as in locality and the details of the molar pattern, it shows affinity with I'laciomys. But there is nothing very essential in the difference of molar pattern, while the general shape of the skull, the external proportions, and the molerate claws are all so much more like Pitymys than Phaiomys, that I provisionally place it with the former, in which it is geographically a connecting-liuk between the European and American members.

## 19. Nicrotus (Alticola) argurus, sp. n.

ㅇ. 102. Ilissar Mts., 100 miles E. of Samarkand. $9500^{\prime}$. 14th June, 1908. Type.

A pale species, with an unnsually long white tail.
Size about as in M. Whanjordi, the only other long-tailed species. Fur fine and soft; hairs of back (in summer pelage) ahout $7-8 \mathrm{~mm}$. in lengeth. General colntr above "ecrudral)"; muler surface white, the slaty bases of the hairs showing through; a line of cream-buff marking the junction of the upper and lower colours on the sides. Hands and feet white. 'Tail unusually long, slender, thinly haired (in summer), lightly pencilled, wholly white above and below. Mammæ $2-2=8$.

Skull not mulike that of M. (A.) worthingtoni, Miller, allowing for the fact that the type is barely aduit. Bullia rather smaller.

Teeth of the typical Alticola structure, but not very highly specialized, as the posterior lobe of $m^{3}$ is not so long as it otten is, and is also, with the rest of the teeth, thicker, its thinness being a characteristic of the most specialized forms of Alticola. Pattern about as in MI. blanfordi *.

Dimensions of the type (barely adult) :-
Head and body 93 mim. ; tail 50 ; hind foot 19; ear 15.5.
Skull: greatest length 2.54 ; masals $7 \cdot 2$; interorbital breadth $3 \cdot 9$; palatilar length 12 ; diastema $7 \cdot 4$; palatal foramina $4 \cdot 6$; upper molar series (crowns) $\tilde{\circ} \cdot 2$.
$H a b$. and type as above.
This striking vole is readily distinguishable by its very long tail from all the species of Alticola except MI. Ulanfordi, which approaches it in tail-length but is very much darker

* Figured by Blanford, J. A. S. B. 1. pt. 2, pl. i. (1881).
coloured, and whose tail has a dark line along the upper surface.

The present is the most western locality at which any true Alticolu has been found, but there is little doubt that Chionomys, the subgenus recently founded to contain the Microtus nivalis group, is the nearly allied European representative of Alticola.

## 20. Ellobius fusciceps, sp. n.

©゚. 69, 70, 72, 80; ․ . 66, 73, 82. Samarkand. $2000^{\prime}$. Black of face extended on crown. Skull short and broad. $m^{3}$ complicated.

Size, as ganged by skull, scarcely larger than in E.talpimus. General colour above buffy, rather darker and more intense than "pinkish buff," passing gradually through dull buffy on the sides to soiled buffy whitish on the belly, the last lighter than in true tulpinus, darker than in rufescens. Face blackish, the black extending further back than in other species and not entirely giving place to the dorsal colour till behind the level of the ears.

Skull comparatively short and broad, zygomata evenly ant widely expanded. Nuzzle short and broad, the incisors rather less projected forwards than usual, their tips about 2 mm . nearer the molars than in other specimens of the same size. Nasals not markedly narrowed behind, their posterior end just level with that of the frontal premaxillary processes. Brain-case smooth and little ridged, even in specimens with the teeth quite worn down. Lambdoidal ridges well marked, nearly evenly transverse, but slightly bowed forwards in the middle third and very much as they are in E. tancrei, quite different to the condition in E. fuscocapillus, intermedius, lutescens, and woosnami.

Third upper molar complex, about as in nos. 9-10 of Büchner's plate, therefore very different from the simple tooth of E. talpinus and rufescens.

Dimensions of the type (an old male), taken in the flesh:Head and body 106 mm. ; tail 13 ; hind foot 21.
Skull: condylo-basal length 31 ; condyle to tip of incisors 32.8 ; zygomatic breadth 22.3 ; nasals $8 \times 3.4$; interorbital breadth 54 ; palatal length 18 ; diastema 11 ; palatal foramina $3 \cdot 2$; upper molar series $7 \cdot 3$.

Hab. Samarkand.
Type. Old male. Original number 80. Cullected 20 th April, 1908.

Lxternally this Eltotius differs from any of the other
described forms by the greater extension backwarls of the dark colour of the crown.

In the skull E. tulpinus and rufescons are smaller, with much simpler $m^{3}$; E. tancrei is larger, with longer muzzle and more forwardy propeted incisors, as are also, with differently shaped lambloidal ridges, E. fuscocapillus, intermatius, lutescens, and woosnami.

## 21. Lepus sp.

8. $27,29,35$; ㅇ. $26,29,38,39,53.30$ to 50 miles W. of Bokhara. $600^{\prime}$.

## 22. Lepus sp.

8. 11.3 ; f. 114 . Hissar Mts., 100 miles E. of Samarkand.

In face of the considerable number of names that have been given to Central-Asian hares, I camot at present determine deffinitely the two speries abtained by Mr. Carruthers. Une of them is no doubt $L$. lehmanni, Sev.

## 23. Ochotona rutila, Sev.

ठ. 119. IIisar Mits., 100 miles E. of Sumarkan l. 9500'.
"Shot ammo rocks: not at all shy; was carrying a lar ge amount of grass." $-D . C$.

## XXXII.-Two neve Bets firom the Solomon Islands. By Knud Andersen.

## Pteralopex anceps, sp. n.

Diamosis.-Dentition less specialized than in Pt. atrota (Guadalcanar, E. Solomon Istandi) ; fur much lonerr; underside of body conspicuonsly paler. II $\boldsymbol{r}$, Bongainville, W. Solomon Islands.
$r^{4}$.- Nore Ptercpine in shape and structure than corresponding tooth of 1'. atratu. In Pt. ancops $\mathrm{p}^{4}$ is one-tifth longer than broad (actual measurements, antero-postenior diancter of crown 5.8 mm ., tran-verse diamet r 4.5 ) ; the anterior basal ledge is narrow, not exten li:ng on the inner side of the tonth round the base of the imer main cusp; the posterior basal ledge less heavy, particularly postero-internally, and not
extending on the imer side of the tooth; imer main cusp not essentially diffirent from that of $p^{\frac{1}{2}}$ of a Pteropus, i. e. it has preserved its character of a longitudinal ridge, is not much shortened antero-posteriorly, and, as in Pteropus, it constitutes the imer wall of the tooth (is not pressel inward, on the crushing surface of the to oth). In Pt. atiatia $\mu^{1}$ is much more conspicuously shortened, being only one-twelfth longer tham broad (actual measurements from four skulls, anteroposterior diameter of crown $4 \cdot 8-5.2 \mathrm{~mm}$., transverse diameter $4 \cdot 7-1 \cdot 8$ ) ; the anterior basal ledge is broad and extends, as a well-marked ledge, on the inner side of the tonth round the base of the imer main cusp, which is consequently cut off from the inner side of the tooth and practically situated on the crushing surface; posterior basal ledge heavy, particularly p.sterointernally, in some individuals showing a very pronounced tendency to extend forward along the inner base of the tooth, nearly mecting and uniting with the imer prolongation of the anterior ledge ; inner main cusp of tonth much more shortened antero-posteriorly, i.e. it has entirely lost its character of a longitudinal ridge and is transformed into a conical cusp.
$p^{3}$ and $m^{2}$.-Differential characters of $m^{1}$ much the same as those described above, under $\mu^{4}$. $\mu^{3}$ is in neither species so much specialized as $\mathrm{p}^{4}$, the differential characters therefore correspondingly less conspicuous.
$p_{3}, p_{5}$, and $m_{1}$.-The bifurcation of the tip of the nuter cusp of $r_{t}$ and $m_{1}$ (one of the most peculiar characters of the genus:) is much less pronounced in Pt. anceps; it is well marked on the inner side (crushing surface) of the cusp, but in the profile of the outer side of $\rho^{2}$ and $m^{2}$ it shows only as a slight depression in the upper margin of the cu-p, whereas in Pt. atrata it is a deep notch. $\mathrm{p}_{3}, \mathrm{p}_{4}$, and $\mathrm{m}_{1}$ are conspicuously less shortened, being about one-half (in Pt. atrata only one-fourth) longer than broad. As in the upper tecth, the inner main cusp of $p_{4}$ and $m_{1}$ is more ridge-like, much less cusp-like (conical), than in Pt. atrata. The posterior basal ledge of $p_{4}$ and $m_{1}$, which in $P_{t}$. atrata is much more developed on the postero-internal than on the postero-external comer of the teeth, thus rendering the posterior margin of the teeth strongly oblique (particularly in $\mathrm{m}_{1}$ ), is in Pt. anceps smaller and more equally developed postero-externally and pustero-internally, rendering the hinder margin less obligue.

Incisors and canines.- Upper incisors and canines, outer lower incisors, and lower canmes heavier than in P\%. atreter ; upper incisors, combined breadth, $10 \cdot 8 \mathrm{~mm}$. $(9 \cdot 7-10$ in four skulls of $P^{\prime} t$. atratu) ; upper canines, vertical extent from
alveolus $10(8 \cdot 7-9 \cdot 2)$, greatest antero-posterior diancter of crown $6 \cdot 2(5 \cdot 2-5 \cdot 7)$.

Fur.-Approximate length of hairs, back 20 mm . (12-14 in P\%. atrata), mantle $30(18-20)$, belly $21(13-15)$. Tibia and metatarsus densely clothed above ; thinly scattered hairs on phalanges of toes; in Pt. atrata the fur extends backward on proximal three-furths of tibia, leaving distal fourth of tibia, metatarsus, and phalanges naked save for some thinly spread hairs. Furred area of back broader than in atrata.

Colour-Blackish tinged with seal-brown; middle of breast and belly light drab with short concealed seal-hrowa bases to the hairs. P\% atrata is practically miform blackish above and heneath, with no trace of drab on underparts.

Size.-Probably as $I^{\prime}$. cutruta. 'The type and only specimen known is slightly immature (evidently very nearly fullgrown ; forearm 137 mm ., in four adult Pt. cetruta 139-14.3.).

Type. of imm. (skin and skull) ; Bougainville, April 1904; collected by A. S. Meek ; B.М. 8. 11. 16. 7.

Remarlis.-The discovery of this species is of particular interest, not only because it is a second form of the peculiarly aberrant genus I'teralopox, which was hitherto known from Guadaleanar only, but also, and chiefly, because it links that genus more intimately to Pteropus. Pterichopectanceps posisesses all the essential dental characters of Pt. atrata, some of these quite as highly developed as the eastern species (enlargement of upper incisors and canines, outer lower incisors, and l's, secondary cu*p of upper canines, \&e.), others decidelly less developed (anterior and posterior basal ledges of molariform teeth, splitting of outer cusp of $p_{1}$ and $\left.m_{1}\right)$, but. at the same time it has preserved more of the dental characters of an ordinary Pteropus (inner ridges of upper and lower molaritorm teeth, less excessive shortening of these teeth). So far as the two latter categories of characters are concemed, it shows one of the stages through which the still more highly specialized P\%, atruta must, in all probability, have passed. Externally, in the distribution, quality, and length of the fur, as well as in the colour of the whole of the upper side, it bears a striking resemblance to Pteropus pselaphon (see my paper on the affinities of Pteralopuc, Ann, \& Mag. Nat. Hist., Feb. 1909, pp. 218-222).

## Hipposiderus demissus, sp. n.

Diagnosis.-A species of the H. diadema group, allied to H. ocearitis (Guadalcanar), but much smaller, and conspicuously paler beneath. Hub. San Christoval, E. Sulumor Islands.

Colour--Expasil colour of upperside duk brown, betwen vandyck-brown and seal-brown, this colume contineal to tips of hairs; middle portion of individual hairs light eeru-dial or whitish ecru-dral); extreme base dark brown. A distinct but not very sharply defined cream-buffy or aearly whitish strine on each side of back along meinbranes. General colun of underside drab tinged with hair-brown, and conspicli,usly lightened with greyish white on sides of b:east and belly; concealed bases of hairs nearly everywhero dark brown.-'The upperside is not essentially different in colour from (only a liftle paler than) that of II. oceruitis; the colour of the underparts is very much lighter.

Aensurements.-Two adult skins and skulls of $I$. Temissus (in parentheses, for comparison, measuremen's of two adult specimens and skulls of $H$. oce-nitis) :-Forearm $6 t^{\circ} 5$ an 1 655 mm . (79 and 79), third metacarpal $5(5 \cdot 5$ and $50 \cdot 5$ ( 54.5 and 56.5 ), fouth metacarpal $45^{\circ} 5$ and $48 \cdot 5$ (54 and 56 ), fifth metacarpal 46 and $46 \cdot 5$ (51 and 52.5 ), lower leg $25 \cdot 5$ ant 2555 (35 and 36). Zygomatic breadth of skull $15 \cdot 2$ and 15.5 ( $17 \cdot 3$ and $17 \cdot 5$ ), mantible, condylus to front of incisons 19 and $19 \cdot \%$ ( $21 \cdot 5$ and $21 \cdot \pi$ ), maxillary tooth-row, $\mathrm{c}-\mathrm{m}^{3} 10 \cdot 2$ and $10 \cdot 2(11 \cdot 3$ and $11 \cdot 8)$, lower tooth-row, exclusive of incisors 11.5 and 11.7 (12.9 and $13 \cdot 1$ ).

Type. ot ad. (skin and skull); Yanuta, San Christoval, 28 th April, 1908; collected by A. S. Meek.

Remarks.-The Solomon Islands are now innown to be inhabited by three perfectly distinct forms of the $I I$. diadema type: the very large and long-legged $I I$. dinops, apparently confined to the New Georgia group ; the small $H$. oceanitis, from Guadalcanar, which in many respects, even in size, is similar to II. pullatus (New Guinea), but considerably different in colour ; and the very small, pale-bellied H. demissus, confined to sin Christoval. The latter species is at the same time the smallest and the extreme eastem representative of the diadema group.-A similar, nr if anything still stronger, splitting of one type of bat into different species, each confined to one island or group of islands of the Solomon Archipelago, is shown by the Pteropus rayneri gruup: Pt. cognatus in sian Christoval, Pt. rayneri in Guadaleanar, Pt. rubiunus in the New Georgia group, Pt. luvellanus in Vella Lavella, and Pt. grandis in the Bougainville group (a sixth species, Ft. cherysoproctus, is found in the Moluceas). The P'leromes hypomelanus group is represented in the Solomon Istands by two species, one western (Pt. colonus, Bougainville gromp) and one central (Pt.solomonis, New Georgia gron:). And as pointed out above, also Pteralopex is differentiated into Ann. \& Mag. N. Llist. Ser. 8. Vol. iii.
two perfectly distinct species, one western (anceps, Bougainville) and one eastern (atrata, Guadalcanar). The faunistic areas of the Solomon Archipelagn indicated by the distribution of the five species of the Pteropus rayneri group are very nearly the same as those recognized by ornithologists (see W. Rothschild and E. Hartert, Nov. Zool. xii. pp. 243-244, 1905).
XXXIII.-Description of a new Cichlid Fish of the Genus Heterogramma from the La Plata. By C. Tate Regan, M.A.

## Heterogramma pleurotania.

Depth of body $2 \frac{2}{5}$ in the length, length of head $2 \frac{5}{6}$. Snout shorter than eye, the diameter of which is 3 in the length of head ; interorbital width $3 \frac{3}{4}$ in the length of head. Depth of preorbital $\frac{1}{3}$ the diameter of eye. Masillary extending a little beyond the vertical from anterior edge of eye ; jaws equal anteriorly; fold of the lower lip continuous; cheek with 4 series of scales; no distinct gill-rakers on the lower part of the anterior arch. Scales $23 \frac{21}{5}$; upper lateral line well developed on $S$ or 9 scales only; lower lateral line vestigial or absent. Dorsal XTI 6; spines subequal from the fourth, the last $\frac{2}{5}$ the length of head. Anal IV 5. Pectoral nearly as long as the head. Caudal rounded. Caudal peduncle decper than long. A dark lateral stripe from eye to base of caudal ; a broad oblique blackish bar from eye to interoperculum ; caudal fin with a few transverse bars or series of spots; outer edge of pelvic fin dusky.

A single specimen, 40 mm . in total length, from the La Plata, received from Herr J. Paul Arnold.

The different coloration, somewhat deeper body, lower spines, narrower interorbital region, \&c. distinguish this species from the allied $H$. corumber and $H$. trifusciatum. A specimen of $H$. corumbe in the British Museum has IV 5 anal rays, and it is probable that in the species here described the normal number is III 6-7.
XXXIV.-On the Toxic Action of the Bite of the Bromstany or South-African Tree-Snake (Dispholidus typus). By F. W. Fitz-Simons, F.Z.S., \&c., Director, Port Elizabeth Museum, Cape Colony.
This is the suake which recent events have made famous all over the Cape Colony. Recently one bit an assistant in our Muscum with nearly deadly effect; then another in our collection of living snakes deliberately swallowed another individual of its own species, almost as big as itself. These incidents have caused heated discussions everywhere, as, in the first place, the Boomslang has been regarded as a nonvenomous snake, and, secondly, it has hitherto been believed that when suakes swallow each other it is of the nature of an accident-as, for instance, when two snakes ssize and attempt to swallow a frog, rat, or some other form of prey, neith:r caring to let go, the bigger snake naturally engulphs the smaller. In the case of the Boomslang referred to, the act was deliberate in every sense of the word.

Some live frogs were introduced into the care containing five of these tree-snakes, one of which managed, by superior agility, to capture and swallow several of the former, much to the amoyance of one of its fellows. The latter worked itself into a state of great excitement and attacked its companion viciously, seizing it in various parts of its body. Eventually it gripped the other firmly by the neck and gradually worked its head forwards until it reached the other's jaws, whereupon it began to deliberately swallow it with a succession of spasmodic gulps, accompanied by heaving, forward movements.

After a lapse of twenty minutes it had swallowed one half of the struggling, writhing victim. I then had it removed and photographed, and, during the process, so intent was it upon the work it had in hand that, the swallowing. process went merrily on, and the photograph shows it in the act of raising its jaw in order to take another mouthful. Bing desirous of preserving these specimens as evidence of the occurrence, I removed a little tobacco-juice with a feather from a dirty pipe and passed the feather between the jaws of the Boomslang.

Almost instantly a curious vibratory thrill passed throngh the snake from head to tail, the muscles relaxed, and the snake lay a lifeless mass within two minutes of the introduction of the tobacco-juice, demonstrating the rapid prussic-acid-like action of this poison upon the vital functions.

This Boomslang was of the striped, black and yellowishgreen variety, measuring 4 ft .9 inches, whilet the victim was the brown variety 3 ft .11 inches long.

The Boomslang is placel in the British Mrusenm ('atalogue of Suaties by ( i . A. Boulenger in the family (inlubrida, series Opisthoglyha, sul,fanily Dipsarlomomphina. The definition of the Opisthoglyphat is "a division of smakes with one or more of the pusterion maxillary tecth growved," most, if not all, being regarded as poisonous to a very slight decree, paralysing their prey before deglutition.

Now tinis is a very important point to hear in mind, viz., one of the Opistloglypha has been classified in many textbooks of science as a non-venomons smake, or one not dangerous to man, as it is my present intention to prove the very opposite.

Sir Antrew Smith in lis 'Zoology of South Africa' remarks: " $A$ s this snake, in our opinion, is not provided with a poisonous fluid to instil into wounds which these fangs may inflict, they must consegucntly he intender for a purpose different to those which exist in poisonons reptiles. Their use seems to offer olstacles to the retrogressinn (retention) (f living mimals, such as birds de., while they are only partly within the mouth; and from the circumstances of these fangs. being directed hackward and not admitting (f) being raisel so as to form an angle with the erge of the jaw, they are well fited to act as powerful holders when once they penctrate the skin and soft parts of the prey which their poseessors may be in the act of swallowing. Without such fangs escapes would be common; with such they are rare."

He gees on lurther to say: "The natives of South Africa regard the Bomslang as poisonous, but in their opinion we cannot concur, as we have not been able to discover the existence of any glands manifestly organized for the secretion of poison. The fangs are enclosed in a soft pulpy sheath, the imner sufface of which is commonly coated with a thin glairy secretion. This scerction may possilbly have something acrid and irritating in its qualities, which may, when it enters a wound, occasion pain and even swelling, but nothing of greater importance."

Naturally I accepted this generally current belief, and in consequence I and my assistants freely handled these snakes, taking no precantions against being bitten, deeming such to le superfluous, until, "like a bolt from the blue," Mr. James Williams, an assistant, was bitten, and came within a hair'sbreadth of losing his life.

During Norember 1907 we had occasion to transfer our
collection of live suakes to their new apartments, and Mr. Williams was carrying a large variegated Boomslang when it suddenly buricd its teeth in the muscles of his bare forearm, just below the elbow-joint. It gripped with great power and held on firmly. We disengaged its jaws, and I suggrested treating the wound, but he would not hear of such a thing, and helieving, as I did at the time, that it was a nonpoisonous snake I did not insist. The wound smarted a little and he went on working. Within an hour a throhbing headache had manifested itself, accompaniel by oozing of blood from the mucous membranes of the mouth, followed by vomiting.

Meanwhile the wound was slowly oozing hloor, and the minscles in the vicinity were somewhit swollen. He was then taken to Dr. Bruce, who declared him t.) be suffering ummistakably from the effects of virulent poison which was seriously affecting the blood and mucous membranes. During the night Williams's condition gradually and progressively hecame more alarming, and he was taken to the Provincia? Hospital the following day in a state of utter collapse. He steadily grew worse, and blood oozed continuonsly from all the mucous surfaces, viz. the mouth, nose, stomach, blakler, and bowels. Then the blond began to ooze into the tissues and cansed large blackish-purple swollen patches under the skin. One eye and its surrounding tissuez, both forearms for two -thirds their length, a portion of the abtomen, hip, and thigh, were all charged with extravasatel bloud, presenting a dreadful sight.

The venom of Jisploblidus typus evidently contains a poison which acts upon the endothelial cefls lining the capillaries. This action is particularly characteristic of the porson of the Crotalinæ and is most marked after poisoning by the South American vipers of the genus Lachesis.

Flexner has given the name "hremorrhagins" to the constituents of poisons possessing this action and regards them as special cytolysins for endothelial cells.

Williams rapidly grew worse after the second day in hospital, severe abdominal pains setting in and inability to retain even water in the stomach. From this time he rapilly sank, and on the evening of the third day after being bitten I went to the hospital, accompanied by Mr. William Armstrong, J.P., who took what we believed to be his uying deposition, the doctor declaring him to be in an extremely critical condition, which might result in death lefore the morning. He lingered on in this state, bordering between life and death, till about the sixth day, when a slow
improvement began to manifest itself, and from this time onwad his condition rapidly improvel, and in three weeck he was discharged from the hospital still in a weak, debilitated state, and although he gradually regained strength, he had r. lapises of slight bleeding from the nutuons membranes of the month, and one eye was nccasionally affected: and even three months after the accident, slight discoloration in the tissues surrounding one of his eyes showed itself for a few days. Apart from this, he has otherwise elitirely recovered his health and strength, thanks to the skilful treatment in the first instance by Irs. Brace, followed by the effective trealment whilst in hospital under the care of Drs. Pottinger and Wallace.

Some years agn a local gentleman was bitten by a Boomslang snake and died a few days later, but the general belief was, and is, that he died of bloud-puisoning consequent upon pricking and irritating the womnd with some foreign sulfstance. A well-kn,wn gentleman, who saw him shortly after heing bitten, says:-" I questioned him as to whether he had experienced any (ffects irmom the bite, and he certainly gave me to understand that he had mot, and attributed the whole truble to the rash use of a needle, and making too deep a puncture with it. 1le told me that he felt quite well as far as his health was concerned, and I was surprised to hear a few days afterwards that his death was attributed to the bite of the Boomslang; I had alwass been under the impression it was a case of ordinary blood-poisoning."

I have made rery careful emquiry intos this case, and it serms the gentlemani at first showed no very apparent signs of comstiturinal disturbance, hut subsequently symptoms set in very similar to those exhihited hy Williams, viz, oozing of blood from the gums and extrayasation of blood into the tissines in various pants of the body, then death. This would seem to indicate that in this case there was a smaller dose of venom discharged into the wounds than was the case with Williams, which took a longer period to manifest its effects.

1 closely crosz-questioned Williams, and he admitted that within half an hour of being bitten he felt a curious, restless, dizzy, and languid feeling, but refused at the time to admit it, thinking it to be due to some other cause, believing so fully that the Boomslang was perfectly harmless. However, in Williams's case the symptoms were such as to leave no possibility of a doubt that he suffered directly ard unmistakably from some deadly and extremely potent venom, and local metdical opinion was unanimous on this latter point.

The Experiments.-It now became imperative to demonstrate whether the Boomslangs were really venomous or not, as this case of Williams would not by any means be accepted by scientific men as proof positive. Naturalists and others handle these snakes and make pets of them under the belief that they are non-venomous, and, moreover, in the public interest this question had to be decided for all time, especially so as the Boomslang is one of the commonest of South African snakes.

The following are the results of the experiments :-
A large brown Boomslang was held by the neck and induced to bite the bared thighs of three fowls in quick succession. 'The first fowl died in 13 minutes, the second in 15 minutes, the third in 3 hours and 4 minutes.

A variegated male Boomslang bit the bared thighs of two fowls within the space of one minute. The first fowl died in 9 minutes, the second in 45 minutes.

A fowl bitten slightly lived two days and died, the wound onzing blood, and the mucous membranes of mouth being inflamed and congested.

A variegated (greenish-yellow and black) Boomslang bit a fowl on the thigh. I killed the snake and injected some of its blood into the victim. No effect. The fowl died in 12 minutes.

A brown Boomslang bit a fowl on the thigh. I killed the suake and injected contents of its gall into the fowl, which died in 11 hours.

Anolher fowl was bitten and injected with the serum of the blood of the snake that bit it. No effect; died in 14 minutes.

A brown Boomslang bit a duck on the thigh. Prowressive exhaustion; slight oozing of blood in mouth; rapid heart's action ; paralysis; death in 17 minutes.

A sccond duck bitten by the same snake immediately after the first one. Same symptoms; died in 35 minutes.

A variegated Boomslang bit a duck on the neck. Within three minutes it fell on its back completely paralysed; lay still for another five minutes; struggled feebly when touched. Died in 19 minutes.

A variegated female Boomslang bit a large cock fowl on the comb. Blood oozed from the cock's nostrils one minute after being bitten. It began to mope, then suddenly sprang. four feet up into the air and fell a dead mass, three minutes after being bitten.
'These experiments were repeated over and over again with all varieties and both sexes of Boomslangs. In all casez
death occurred 11 ithin 20 minutes of the first lite ; the $f$ wls and ducks which were sul, iected to the second bite from the same snake usually lived from 1.5 minutes to two homrs; not a single fowl recovered.

The fowls and ducks scemed to suffer little or no pain beyond irritation at seat of puncture for a minute or two. Within two or three minutes they show unmistabable signs of collapse, and with a spamodic jork or two would suddenly expire. In some cases complete prostration would supervene five or ten minutes before death.

A few higher amimils of greater vital tenacity were als. experimented with, and the characteristic shaw onzing of blood from the fanc-punctures when noticeable, as was the case with TVilliams. The ammals in every cate gradually grew wome, and after about 12 hours were chloroformed, it being evidnt they were slowly sinking unler the potent effects of that subtle, death-dealing venom.

Some folks will regard these expermmis as crnel, but they wore combucted in order that human life might be saved, fur in no other way cond I have rapialy and conclu-ively demonstrated to the public that the B omslans is mot only venomons, hut exceedingels so. I can go further, and clam that the vensm of the B windang is ergual in itsoleath-dealing fower to that of the dreadeal (inbra (Nuenflece) and Linghais (Sipedon hremuchates), for I foreed these smakes to bite wover fowls hy haring the thigh and holding the snake's heal close up against the flesh, when in every instance it would deliver a full and complete bite.

In all cases I made the snake give a secon l bite to make ahsolutely sure a lethal dose had heen injecten. The fowls all died in from five to twenty minutes - the average being fitten minutes. In every case fowls bitten twice on the hared thigh by puff-adders (Bitis arietuns) survived from f ur up to twelve hours, some recovering completely. The majority bitten by night-adders (C'ussus rhombentua) were wry sick for a coiple of days, then recovered, one or two dying after twelve hours.

It will be seen by the results of the abave experiments that the bite of the Bomslang dentroys the life of a fowl just as rapilly as that of the Cobra, and that the venom of the pufferalder is in comparison very slow in its action and not nearly so virulent.

The reasons why the Bromstang d es not always inflict a renomous bite are two. The fangs are groned and compatatively small, and if the bite is dilivered the ugh clotining

The venom is alsonleed by the material and the fangs barely scoach the flesh. Secondly, the fangs are sot halfway lyank in the upper jaw, and are thice in number on each side, exactly under the eyes, and naturally unless the Boomslang's arip he full and complets these fangs do not penctrate the Alsh. During my experiments I uliserved that the Boomslang in every case made as good a grip as possible on the animal, then almost instantly, with a heaving, forward movement and disengagement of the teeth of the upper jaw fiom the victim's flesh, twould take a fresh and more secure hold, the upper jaws in which the fangs are set being capable of leing pushed downwards, exposing the fangs and forcing their points forward: the jaw then closes with a snap and the snake worries the flesh, with the evident intention of forcing the venom into the punctures, as well as cularging them for the freer ingress of the poison.

Sir Andrew smith, the great haturali:t and authom, says in his 'Zoolngy of South Africa': "As this suake, in our ghinion, is not provided with a perisonous fluid to instil into the wounts which the fanges may inflict, they must consuquently be intended for a purpose difterent to those which exist in ! oisonons reptiles. We have mit been all, to discove: any glands manifestly organised for the secretion of poison."

I was by wo means inclimed to accept this as funal, and careituly dissected the heads of several Boomslangs, and in "very case I discovered a small gland on cach side of the head, lying immediately behind and above the gro oved fangs, and it could be clearly seen that it had a comection with the cavity at the root of the grooved fangs and that it was the gland which secreted the sticky fluid found in the sheath enveloping the fangs.

The next move was to ascertain if the organ was really a gland capable of secreting any fluid, whether venomous on mot. Dr. Rotinson, of the Teterinary Institute at Crahamstown, made a microscopical examination of its structure, am? repors it is uncoubtedly glandular amd capable of secreting. Subsequent experiments by myself hear ont this statement, and, morcover, mader the michorcope, a sticky, colourlass flud, identical with that found in the sheath, was observed in the structure of the glands and was pressed ont upon the microscopical slide with the tip of a lancet. Small pieces of these glands were cut up and inserted under the skin of bahhit, and slight pressure applied for an instant. Within 15) min,utes the rablits were dead. One was otricken with
complete paralysis within five minutes of the insertion of the fragment of gland.

These experiments conclusively prove these glands to be capable of secreting a very virulent venom, and that they are the glands which produce the glairy sticky fluid within the sheaths enveloping the fings. These poison-glands are comparatively small, less than a sixth the size of those of a puffadder. That they secrete a venom, potent and virulent, seems now hardly to admit of a doubt. Sir Audrew Smith clams the fangs are simply used for the retention of the prey, such as birds, which would otherwise escape. 'This is patly, but not wholly so. When a Boomslang seizes a live lind it grips with great tenacity. The bird struggles frantically for a minute or two and is then overcone by the potent action of the venom injected through the snake's ghooved fangs. It then hisurely proceeds to swal'ow the birds, feathers and all.

Bomslangs are very timil creatures and will not bite unless rounhly handlul, or an attempt be mate to seize them, hence the reason so few poople are Liten by them. I have handled these smakes freely in the past, aml friends have done likewise without any attempt on the part of the snake to lite. Bumslangs are csentially tree-snakes, being quite at home in the foliare of the trees, through which they can thavel with great rapidity. They vary in colvur, some heine a bright greenish yellow, banded with hack; others are vivid grass-green, banded with black; whilst othere, again, are dark uniform brown alone, shading into paler on the aldomen, some specimens approaching the greyish tint. The coloration of the female is not quite so brilliant as that of the male. This is particularly moticeable in the greenish-yellow and black varieties.

Buomslangs frequently descend to the ground in search of food and may otten be seen basking in the sun on the bare ground in the vicinity of some thicket, into which they rapidly glide if disturbed. In captivity they become very tame and will take food from the fingers. Thoee in the Port Llizabeth Museum readily eat dead food-such as birds, chameleons, lizards, and frog:- whether fresh or stale.

On several occasions female Bommslangs, both Variegated and Brown, have laid batches of egos varying in number from a dozen to twenty-three, containing a yellowish fluid, with no sign of incubation having already begun.
XXXV.-Preliminury Note on some Fishes from the Irish Atlantic Slope. By E. W. L. Holt and L. W. Byrne.

These fishes were collected by Messrs. Farran and Kemp in the 'Helga' in August 1908.

## Scylliorhinus indicus, Brauer.

A young example, S. R. 593, 6/8/08, $50^{\circ} 31^{\prime} \mathrm{N} ., 11^{\circ} 31^{\prime} \mathrm{W}$., 670-770 fathoms.

We are indebted to Mr. Regan for the determination. The species is otherwise known only fro n the Pacific.

## Rhinochimera atlantica, sp.n.

An adult male, measuring 850 mm . to the origin of the dorsal lobe of the caudal, and 1165 mm . in total length, including the caudal filament. S. R. 593.

Diagnosis.-Adult male with the snout (measured between verticals from its tip to the origin of the vomerine dental plates) as long as the distance between the dorsal insertions of the pectoral and ventral fins and somewhat longer than the base of the second dorsal fin. Second dorsal fin with base about halt as long as the distance between the gill-opening; and the origin of the ventral lobe of the caudal fin. Posteriur ventral claspers terminating in subconical slightly volute clubs. Vomerine dental plates deeply notched on their cutting-edges.

The above characters, especially the relative shortness of the base of the second dorsal fin, serve to distinguish adult $R$. atlantica from adults of the very closely allied $R$. pacifica (Mitsukuri). Nothing is known of the young of either species. Harriotta raleighana, Goode and Bean, known only from immature specimens, is stated to exhibit a progressive development of tritoral elements on the dental plates. In the absence of any evidence of the condition of the plates in young and half-grown lihinochimera, in the adults of which there are no tritors, it is unsafe to argue that Rhinochimera is the adult of Harriotta, which in respect of other characters seems possible enough.

Messrs. Farran and Kemp have collected five ego-purses (hetween 550 and 720 fathoms) which appear to be identical with those obtained on the American side of the Atlantic and tentaively assigned to Harriota. They closely resemble but are much smaller than the egg-purse of $h$. pacifica, which is
evidently a much larger fish than its Atlantic congener. Irecieply similar differences are exhilited by the proses of - limuria monstionsa and its larser Pacific representative C. phuntesmu, while the same comprarison may be mate lewteen a pair of purss, 125 mm . long, which we refur (w ('. miveritis and the fursm of the Pacific C. mitsulurii.

## Nesiarchus nasutus, Johnson.

A specimen, 730 mm . long, S. R. 593.
Irevionsly lanown from the coasts of Malita and Putu al.

## Hoplostethus atlanticus, Collett.

Suporal, of which the largest are masive inliviluals
 400-510 fathoms, and S. R. 593.

IV are inlebted to Ar. Rogan for the detmmination.
locriously known from the Azores and Cape of (ix ol Hope.

## Servivomer beani, Gill and Ryder.

A mangled fish, from S. R. 593 , seems to be reforable to this specine, which has a wide distribution at suitable depths in the North Atlantic.
XXXVI.-Neu Ajrican Palebrtumic Diptera in the British M/uscun (Sutural History).-Part VI. By ErNeser L. Austen*.

## Chironomidæ.

## Cieratopogonines.

Genus Culicoides, Lati. $\dagger \dagger$
Culicoides yrahamii, sp. n.
§. -Tength ( 13 specimens), incinsive of head, 1 mm . th just over 1 mm .; length of wing 1 mm .

* For Parts I.-V. see Ann. \& Mag. Nat. Hist. ser. 8, vol. i. pp. 209228 and 401-428, and vol. ii. pp. 94-116, 274-301, and 352-356.
+ Colntred fimeres of the three -pucies of this grans deariled lalow will appear shortly in an official whine gatithen 'Illustation of Aftan 'Blood-sucking Flies,' with notes by the author.

Colour of body (in (ried specimens) mouse-grey * ; urinys bight sepiu-coluncol, with three large clear spots on cosial margin (distal spot close to tip of winy, above end of "piner branch of fourth lomgitudinal vein), and tiro less sharinly definerd pule spots on hind margin, one within fork of titth Tongitudinal vein, the other in anal anyle; in middle of costal margin is a conspicuous clore-brown elonyate blotch, corverin! distal third of first lomgitulinal and grenter part of third longitudinal reins, white on busal thirel of costal margin is an elonyate dark blotch of less intensity: the two distol clear spouls are sepurated by a moderately dark quadiate blotch; heod large, prominent, not bent dorrn bencath anterior portion of thorax ; tibice with a conspicuons pale band at base.

Head: palpi sepria-coloured; first joint of entemere dark brown, flagellum sepia-coloured, clotherl with pale hairs. Thorex: dorsum elothed with scattered yellowish hairs. Abdomen clothed with brownish hair. IVägs: upper portion of distal extremity, above upper branch of fourth longitudinal rein, clothed with scattered and minute black hairs; third longitudinal vein comected with first longitudinal by a cross-vein, fourth longitudinal vein bifureating a little before middle of wing. Halteres straw-rellow, knobs large, elliptical. Leys sepia-coloured, clothed with pale yellowish hairs, tibie with a narrow cream-coloured band at base, hind tibir also with a similar band at tip.

Aslanti, Southern Nigeria, Congo Free State, Uganda : trpe and three other specimens from Obuasi, Ashanti, 17. xi. 1907, "canght on the arm of a European " (Dr. II'. MI. Graham) ; additional material from Forcados, S. Nigeria, May 1908 (G. C. Dudgeon), Cross River, S. Nigeria, $190 \mathrm{G}^{\prime}$ (Dr. R. W. Gray), Binza, a small village near Leopoldwille, Congo Free State, 13. xii. 1903 (the lute Dr. J. E. Duttom: und Dis. J. L. Todd and Cuthbert Cleristy), and Bwamba Country, Semliki Valley, S.-W. Uganda, 2700 ft. , " iu forest," 1905 (M. T. Dawe).

This tiny midge, which is evidently very widely distributed in Tropical Africa, would appear to be the African representative of the equally bloodthirsty Culicrides curius, Winn, of Europe ; the wing-markings of the two species are identical, but C. grahumii can at once be distingnished by its much smaller size, paler antenue, and much more conspicuous pate bands on the tibire: British specimens of C. rarius exhibit nothing more than faint indications of pale tibial hands.

[^46]Notes supplied by collectors show that C. grahumii is a troublesome pest, its bites, like those of other midges, producing irritating wheals on the skin: fuller information will be given in the author's forthcoming work on 'African Blood-sucking Flies.'

## Culicoides brucei, sp. n .

\&.-Length (3 specimens), exclusive of head, 1 to $1 \cdot 6$ mm .; length of wing 1.5 mm .

Colour of body (in dried specimens) monse-grey or olivebrown, with more or less distinct dar liown lomgiturlinal marliings on dorsum of thorax: hecad smull, in dried specimens bent dowmeards beneath anterior portion of thorax, so as to be invisible from alove; wings yellomish, semitransparent, sparsely clothed with minute brownish hairs, and spotted and blotched with dark brown and mouse-yrey, branches of fourth and fifth longitudinal veins also bordered more or less with mouse-grey.

Head: pulpi dark brown; basal joints of antenne dark brown. Thorax : dorsum in some specimens in front with a median dark brown mark, and a little further back a pair of dark brown admedian stripes extending somewhat beyond middle of dorsum ; behind posterior ends of admedian stripes and a little nearer middle line a pair of somewhat curved dark brown flecks may sometimes be seen. Abdomen clothed with brownish hair. "Iinys : darkest and most conspicuous marks are two on and adjacent to costa ; of these, one consists of a narrow, clongate, clove-brown mark reaching from ensta to third longitudiual viin, and extending a little way on each side of cross-vein between first and third longitudinal veins; the second is a large, oblong, dark brown mark, with its inner margin somewhat concare and its outer margin more or less convex, situate midway between former mark and tip of wing and reaching from costa to upper branch of fourth longitudinal rein ; tip of wing above upper branch of fourth lougitudinal vein is occupied by a mouse-grey blotch; in distal fourth of wing are two mouse-grey quadrate blotches, of which one comects the mouse-grey borders of the two branches of the fourth longitudinal vein, while the other extends from lower branch of fourth to mouse-grey border of upper branch of fifth longitudinal rein; remaining markings consist of a sharply defined, mouse grey, oval spot in centre of cell enclosed by branches of fifth longitudinal vein; a small, mon=e-grey, quadrate blotch below cross vein
connecting first and third longitudinal veins, and between third rein and upper brauch of fourth ; a large, pale mousegrey, roughly quadrate blotch in proximal third of wing, extending from costa to fourth longitudinal vein (within limits of this blotch costa and other veins passing through it are darker) ; a similar but narrower blotch in centre of fifth longitudinal vein, with an ill-defined extension into anal angle, and a more or less well-defined, mouse-grey, oval spot on proximal side of lower branch of fifth longitudiual vein: fourth longitudinal vein bifurcating a little before middle of wing. Halteres sepia-coloured, proximal twothirds of stalks cream-buff. Legs sepia-coloured, clothed with brownish hair; tibix cream-buff at extreme base.

Uganda: type and four other specimens from the vicinity of the Mianga River, July 1903, "biters " (Colonel Sir David Bruce, C.B., R.A.M.C., F.R.S.).

The pattern and diffuse character of the wing-markings will serve to distinguish Culicoides brucei without difficulty from either the foregoing or following species.

## Culicoides milnei, sp. n.

ㅇ.-Length (3 specimens), exclusive of head, $1 \cdot 5$ to 1.6 mm . ; length of wing 1.6 mm .

Coluur of hody (in dried specimens) dark brown, with a median grey patch on hinder portion of dorsum of thorax; head small, in dried specimens bent downwards as in foregoing species; wings, except basal sixth, which is cream-coloured and semihyaline, sepia-coloured, strongly iridescent, and marked with sharply defined small light spots; three cream-coloured transversely elongate spots on costa, separated from cach other and from base of wing by quadrate sepia-coloured blotches, somewhat darker than remainder of winy ; other light spots smaller, more rounded, and milky rather than cream-coloured.

Head: palpi dark brown; first joint of antenne mummybrown, flagellum isabella-coloured, clothed with yellowish hair, last five joints darker. Thorax: dorsum sparsely clothed with dark brown or brownish hair. Abdomen clothed with brownish hair. Wings: costal spots as fol-lows:-lst, starting from costa abore base of third longitudinal vein, crossing first and base of third longitudinal veins, surrounding anterior transverse vein, and extending to fourth longitudinal rein; 2nd on costa at point where third longitudinal vein enters it, extending downwards to about three-fourths of distance between costa and upper
branch of fourth longitudimal vein (greater part of this spot lies beyond third rein, but it aloo extends into space between tips of third and first longitudinal veins) ; 3ral spot on costa midway between secomel spot and tip of wing, its lower cestremity somewhat closer to upper branch of fourth loagitadial rein than is lower extremity of second spot. Remaining spots as follows:-a group of fone in distal fourth of wing, consisting of a pair of apots in middle of lower branch of fourth longitudinal vein (one sprot abore, the other below the bram h, with which ther are in (ontact), and a second puir (in which the spots are also on rither sule of the lowar branch of the fouth longitudinal rein, but wider apart) between former pair and margin of wing: a romnled spot on himd marain, in cell caclosed by the branches of the fifth lougitudinal rein, nearer uppor branch than lower ; two spots belos tifth longitulinal vein, one close to rein some di-tance lofare it forke, the other on or near hind margin and a little lurther from bas: of wing ; near athal angle may be a trase of a third amd much smatlee spot; lastly, thore is a -monewhat chongate spot, semetimes fairly large, extenting from baise of lower brawch of fourth to that of uppre brauch of fifth longitudinal rein. Thime longitudinal connected with first longitndinal vein by a crossrein; fonth lomyitulimul vein bifurcuting in middle of winy; distal portion of wing sparsely clothed with minute brownish hairs. Ifulteres: knots large, sepia-coloured ; stalks and tips of kuobs cream buff. Legs sepia-colowed, tursi, a narrow band at base of tibie and tips of hind tibiee cream-buff.

Lant Thica Protectorate: type and two other specimens from Nairohi, $5000 \mathrm{ft}$. , 4. v. 1906 (Di. A. D. Milne). According to the donor this species is prer lent at Nairobi in the rany scason, when it invales bedrooms at night. Writing on Aug. 21, 190(;, Dr. Milne stated that these midges abound in the grass on the Athi Plains during the wet weather, and that, so far as he wate awace, there was nothing to conneet them with any disease of human beings or domestic animals.

Owing to the pattorn of its wing-markings, Culicoides milnei camot be confused with either of the forerging species: as affording a further means of distinction, the position of the fork of the furth longitullinal rein mar also be noted.
XXXVII. - New Gonera and Species of Blood-sumtinng Muscidx from the Elhiopian and Oriental Regions, in the British Musenm (Nutural Historiy). By Erxest E. Austen.

Stomorydine.
Gehus Lyperosia, Rond.
Lyperosia punctigera, sp.n.
p.-Length ( ${ }^{2}$ specinens) $3: 2$ to 3.25 mm ; width of head 1.2 mm ; width of front at vertex 0.1 mm . ; length of wing 3.5 mm .

Thorax greyisisk, with ligliter medion Iongitudinal stripe and darker marlingys behind suture; aldomen olive-grey *, dorsum with a sepiu-colunred elonyate median spot or tapering stripe on second and followin! segments, sucond and thirld segments in addition euch with a pair of large and conspicunus, transversely oval, clove-brown si;ots; vinus hyaline, ivinescent; legs cream-buff or butf, hind tibice dusk!, tips of hind femora especially on inner side, hind tersi, and last three joints of front and middle tarsi dark brown.

Head light grey, front relatively broad, sides of front (parafrontals) very conspicuous, frontal stripe clove-brom, its sides nearly parallel, though slightly outwardly convex in middle. vertical, frontal, and orbital bristles dark brown; proboscis short, horizontal portion approximately equal in length to vertical diameter of head, mummy-brom, distal portion immediately before labella dark brown; palpi not or scarcely projecting beyond proboscis, not clavate, or at least sides of distal half parallel, buff, tips brown, clothed with short black bristles, coarser, longer, and especially conspicuous at tips ; antennce dark brown, upper distal angle of second joint cimmamon-rufous, arista brown, extreme base and a band before middle pale, upper side with about six hairs. Thorax: humeral calli and anterior end of median stripe of a lighter grey than remainder of dorsum; in front of transverse suture an ill-defined stripe of darker grey on each side of median stripe, continued behind suture as a tapering mummy-brown stripe, which terminates at a point midway between suture and front margin of scutellum;

[^47]between termination of mummy-brown stripe and lateral margin on each side is an clongate fusiform mummy-brown spot; pleure light grey ; scutellum of same colour as portion of dorsum in front of it ; lairs and bristles on thorax black. Abclomen : elongate median spot on sceond and third segments shaped like a truncate isosceles triangle, with base resting on front margin of segment and apex not or scarcely reaching hind margin; median spot on fourth segrnent narrower, in shape of a slender, tapering, longitudinal stripe, on each side of which is a roughly quadrate patch of light mumny-hrown dots, which may be more or less conflume ; clove-brown transpersely oral spots on second and third segments not in contact with front, hind, or lateral margins; hair on abdomen uniformly dark brown. Winys: veins brown ; first posterior cell distinctly contracted at tip ; posterior transverse vein strongly bent outwards.

Uganda : two specimens (co-types) from the Nile Prorince, June 1906 (the late Dr. II. A. Densh(min). The collector's ficld-note on this species is as follows:-"These flies were noticed in great numbers in one camp only near the Nile, and were very troublesome to my boys carly one sumy morning ; they clustered thickly on any small sore, and quickly filled themselves; thongh preferring to feed in this way, they seemed also to insert the proboseis into sound skin."

The conspicuous abdominal markings described above are an unusual feature in Lyperosiu, and will cnable the present species (of which a coloured figure will appear shortly in an official publication) to be distingrished without difficulty from any of its congeners hitherto described.

## Genus Stygeromyia, Austen.

(Amm. \& Mag. Nat. Hist. ser. 7, vol. xix., May 1907, p. 145.)
Styyeromyia sanyuinaria, sp. n.
ठ ㅇ. -Length, б (l specimen) 7 mm ., f ( 1 specimen) 6.75 mm . ; width of head, o 2.6 mm ., of 2.4 mm .; width of front at rertex, $\delta 0.5 \mathrm{~mm}$., i 0.6 mm . ; length of wing 7 mm .

Grey, clothed with black hairs and bristles, of somewhat darker than $\sigma^{\text {: }}$ closely resembling Stygeromyia maculosa, Austen (loc. cit. p. 447), in general appearance and also in markings of dorsum of thorax, but distinguished by abdomen being without sharply defined mummy-brown spots, not in contact with hind margins of segments, and by proboscis, except
tip, beiny orame-buff or actiraccous-buff, instear of duts chestnat-brown; dorsum of abdomen with a nurroue, durit broun, median, longitudinal stripe, and more or less distinct dark blotches on hind borders of second and third seyments.

Head: face and front yellowish silvery in $\delta^{3}$, darker, shimmoring yellowish in of in both sexes jowls yellowish grey, occiput grey ; frontal stripe walunt-brown, in o very narrow, about half as broad again as orbits, its sides straiglit and parallel, in $\&$ rather less than twice as broad as orbits, widening very slightly below, its sides straight; probuscis' slightly decper at hase in $\delta$, labella shining clove-brown on outer side; palpi buff, agreeing with generic diagnosis, clothed on outer side with black bristles; wintenuce similar to those of S. maculosa, first and second joints and base of third joint on iuner side below cimamon-rufous, remainder of third joint dark brown, greyish in certain lights, arista dark brown, with 12 hairs. Thorax: markings on dorsum dark brown to dark cinnamon-rufous, somewhat lighter than in S. maculosa, but preciscly similar to those in that species in general arrangeinent, median stripe in $\sigma^{\pi}$ only visible behind transverse suture, and nut reaching inner dorsocentral bristles, median stripe in of apparently entire, extending from frout to hind margin; scutellum yclowish at tip, and also in centre of disc in case of ot, in which it is also slightly brownish in contre of base, when viewed at a low angle from behind (scutellum of trpe of of damaged). Abdomen: median dorsal stripe commencing on first seginent close to hind margin, broadest on second segment, becomiug successively narrower on following seginents, cxtrem ly slender (linear) on fourth segment in $\delta$, indistinctly interrupted on hind margins of second and thitd segments, and not reaching hind margin of fourth segment; hind margin of first segment somewhat infuscated, at least in $o$. dark brown blotches on hind borders of second and third segments not in contact with median stripe, but situated one on cither side of middle line, between median stripe and lateral margin, much more distinct and larger in $f$, in which they are roughly triangular and extend forwards beyond middle of segment, in $\delta$ less deep, ill-defined and dying away in tront on second segment, and on third segment forming an interrupted transverse band; skin clothing venter bright buffyellow, small median oval seutes grey. W'ings: in J, venation and opening of first posterior cell preciscly as in S. muculosa $\delta^{\delta}$; in $\circ$, bend of fourth longitudinal vein somewhat more abrupt and opening of first posterior cell slightly wider. Hulteres cream-buff. Legs: in す, coxæ grey, trochanters
ochraceous-buff, front fomora and tibise buff (front tarsi aus) remainder of lers miwing in type) ; in of, (oxie and trochanters as in of, femora ochraceou-boff, hind femorat darkish grey on onier side on rathor more than di-tal half, tibie bult, middle and hind pairs more or leas greyish, all tarsi dark brown ; hairs and bristles black.

Congo Free State and Nya-aland Protectomate: type of ठ from linwe, We-t Lualaba, Katanga District, Congo Free State, March $100($ ( 1 i, A. Yule Merssey) ; type of F from Monkey Bay, Lake Nyasa, Nyasaland Protecetorate, 21. iv. ionos (Comptain Hullum Mardy, R.A.M (\%). Writing on Ang. 9, 1 leot, with reference to the specimen taken ly him, Dr. Lale Massey rematked:-"()n gringover my notes I find that this fly was taken within half a mile of my house at Ruwe, in open busl and on high gromed. My attention was attracted by its hiting me on the hand, catusing pain similar to that produced by the bite of a Tectse: this was the only specimen seen on that oceasion. The fly was canglit hint a few hmodred yards from the catele livaal, lout I have no evidence that it lites cattle. I few lays later I saw two specimens, eridently of the same fly, but failed to catch either; they were very quick in their movements: I have not met with another specimen since."

As may possibly lie remembered, in default of actual observations, the blood-sucking habit of Styyeromyia maculost, Austen (the trpe of the genus, deseribed from a specimen from Little Aelen, Arabia), was inferred "from its evident affinities and from the shape of its proboscis" (cf. Austen, Ann. \& Mag. Nat. Hist. loc. cit. p. 448). It is therefore gratifying to find that the inference in question receives collateral support from Dr. Yale Massey's personal experience in the case of the present species.

## Genus Hematobia, Rob.-Desv.

## Hæmatobia sanguisugens, sp. n.

ठ. -Length ( 6 specimens) 5.5 to 6 mm .; width of heard 1.75 to 2 mm . ; width of front at vertex 0.25 mm . ; length of wing 5 to $5 \cdot 6 \mathrm{~mm}$.

Olicaceous-grey or brounish grey, with clove-brown markings : dorsum of thorax with two pairs of clove-brown longitudinal stripes (outer stripes broader and widely interrupted at transverse suture), and a less sharply defined median stripe; dorsum of abdomen with a clove-brarn median longitudinal stripe, extending from front margin of second to beyond middle
of fourth serpment, narrowly interrupted before hind maigins of second and third segmonts, a pair of ticnsversely clongate duskiy blotches on first semment, a puir of larye clorc-bioun spots an secomb segment, and a pair of similar but smaller spots on thirel segment; winys slightly infuscated, liyht sepiacoloured ; leys clove-broun, buses of tibice ochraceous-buff.

Head: face and sides of front bright yellowish grey, occiput dark grey, frontal stripe clove-brown, hair and bristles black; palpi tawny, clothed on onter side with black bristles, tips strongly spatulate (as in II. stimuloms, Mg.), extreme tips sometimes brown ; proboscis clove-brown ; anterme, including arista and its hairs, clove-brown, under side of arista usually with four hairs. Thorax clothed exclusively with black hairs and bristles; dorsum lighter grey on front margin and humeral calli, admedian stripes extending from frout margin to about half-way between transverse suture and presscutellar groove, portion of outer stripes behind transerse suture extending somewhat further back, median stripe usually extending from front to hind margin, but its anterior extremity sometimes indistinct. Abdomen clothed exclusively with black hairs, median longitudinal stripe on dorsum regularly diminishing in widh from front to rear, dusky blotches on first segment clove-brown, but lighter iu tint than spots on the two following segments, spots on second sesment triangular in shape, near but not in contact with hind margin, spots on third segment rounder, sometimes quite small. Winys: veins for most part dark brown, first longitudinal vein cither entirely bare or at most with one or two minute black bristles near base, third longitudinal vein with three or four very minute black bristles at base. sifuamee: anterior squama cream coloured, shining and iridescent, posterior squama buff. Halteres buff. Legs clothed exclusisely with black hair and bristles, femora and tibire greyish beneath.

India: trpe and five other specimens from Kasauli, Punjah, 190\%, "on cows" (Lieut.-('olonel F. II'grille 'Thomson, I.1I.S.). The donor's field-nute runs:-" Caught on cattle: the flies sucked the animals, and their abdomens became distended with blood. I have never noticed them biting man."

Hematobia sanguisuyens of resembles the of of the European H. stimulans, Mg., very closely, but is distinguished by its usually =omewhat smaller size (average length of $60{ }^{\circ}$ $5 \cdot 75 \mathrm{~mm}$.), by the median dark dorsal stripe on the ablomen being practically contimons throughout its extenit instead of ndedy intermped before reaching the hime margine of the
second asd third segments, by the fourtls aldominal secement in the $\delta$ being always without a pair of dorsal spote, and by The first longitudinal vein lemg either entirely bare or having at mosi one or two minute bristles, instead of a row of bristles conspicuons under a strong lens when viewed at a low angle from the direction of the hind margin of the wing.

## Bdellolarynx*, gen. nov.

Simull, stoutly bwitt, thick-sct flies, closely allied to Heematobia, Rub.-Desse., but distingu: cishuble as folloms:-No seaual contour-dimorphism (unless it be in wings) : jrout farial angles, end anterion margin of buccul cutil! liss purminont: jouls discenciing comsiderahiy bectind, instead of nearly hurizoutal, but basi-nrcipital regism murh less protuleciunt; bristles belome fanial angles small and fine, instrud of reluituedy marse; in 子, Fioml wider, witl: "pper inner mastyins of eypes more nearly firullal, less "flpivaimute in midrlle of fromt : arista fiathered nbove with comsiderall!! lomger hairs, wand belorr with about sie fuirly lomy hairs: first and third lonyitudanal veins ontirely bare, without bristles at base.

Hoad: perfpi spatulate at tips; probroscis as in Incomatulier, slighty tapering, proximal two-thirds somewhat thickened. Tharucie bristles:-- Humeral, 2. Post-humernl, 1. Noto-
 Post-alur, 2. Doison-centicul, 5 i2 in front of and 3 behind shtur-may be difficult to distingui:h, (spectally in of). Inner vimso-cinliol, 1 (sometimes :2 in Z). Scutellar, 4 ( 1 mel lasal, 1 hasal, 1 discal-sitnated close to lateral mar(:3n, 1 apical). Mespleural, about 10 or 12 . Sternopleural, 1: 1.

Himgs: shape of first porterior cell similar to that of sane cell in wing of Hemutolia, isut bend of terminal portion of fonirth longitadinal wein somewhat flatter and less abrupt.

Bidell,lurymax is distinguished from Itematuluasca, Bezzi, by the palpi being mach more spatulate at the tips. lyy the arista having a greater number of hairs below, and, in the wing, by the shape of the fir-t posterior cell and the course of the terminal portion of the fourth longitudinal sein (in Hemalobo.ca the latter details are the same as in Stygeromyiu, Austen).

Typical species, Bdellularynx sanguinolentus, sp. n.

## Bdellolarynx sanyuinolentus, $\mathrm{sp} . \mathrm{n}$.

d f . -Length, of ( 3 specimens) 4.75 to 5 mm . $f$ ( 4

specimens) 3.5 to 4.25 mm ; width of head, of 1.8 mm ., of $1 \cdot t$ to I © mm . ; width of front at vertex, © 0.2 mm ., ㅇ. 0.5 to 0.5 mm . ; length of proboscis 1.4 mm . ; length of wing 4 to 4.8 mm .
nisuse-yrey or slate-grey, clothed with short black hair, bristles also black: palpii buff; dorsum of thorax with a pair of extremely narrow, widely separated, parallel, lomyitudinal, admedian, blackish stripes, a somewhat trianyular blackish mark extending backuards from inner end of each humeral callus, and an elongate Ulackish streak in " line with latter mark behind transicres suture (two outer marks less distinct in \&) ; dorsum of abdomen with a narow, interripted, lonyitudinal, median, clore-browen stripe, and, onsecond and third sergments, puired transecise, roughly triunguiar, c'ore-brown blotches, the puir on second segment especially large; winys hyaline or tinge: with tawny olice in d, hyaline in of ; femora grentish clove-broun, cestreme tips ochruceous-buff, , we or more puirs sometimes more or less brouniash except at buse, tarsi dark brown.

Hecul: frontal margins and sides of face light grey or yellowish grey ; fiontal stripe clove-brown, in $\delta^{\text {o }}$ narrow, somewhat attenuate in middle, where its width is approximately equal to that of frontal margin, in of broad, at least $t$ wice or rather more than twice as broad as frontal margin, with its outer edges convex; palpi clothed ou outer side with black bristles; proboscis hurut umber-coloured, dark brown at tip, projecting slightly beyond palpi ; antennce, inchding arista and its hairs, clore-brown, arista with a lighter band. Thorax: admedian stripes not diverging pusteriorly, sharply defined from front margin to a point about midway between transverse suture and presentellar furrow, after which their continuations to presentellar furrow are broader and less clearly marked; transverse suture blackish; thoracic markings not so conspicuous in of as in $\delta$. Addomen: anterior margin of second and following scgments black and shining, broader towards sides, especially conspicnous in of median stripe commencing on front margin of second and es.tending to or not quite raching middle of fourth segment, widely interrupted before meeting hiud margins of second and third segments; dorsum of first segment in of sometines with a pair of clovebrown blotches, much smaller than those on two succeeding segments ; dorsum of fourth segment in some specimens Whth traces of a pair of small dark spots; venter yellowish grey, median scutes clore-brown. Siquane and halteres cream-buff. Leg.s: in one female posterior femora are
entircly ochraceous-buff, except for a brownish blutch just before distal extremity.

India and Ceylon: type of of from the environs of Calcutta, India, 8. ii. 1905 (E. Brumetti) ; type of of and another of from Mussonic, United Provinces, India, September 1906 (F.M. Howlett) : additional specimens from Allahabad, United Provinces, India, (j. x. 1:3(0) (F. M. Howlett) ; Sylliet, A-sam, India, 13. is. 1905 (Major Hall, I.M.S.) ; and IIenaratgoda and Haldumulla, Ceylon, 7. ii. \& 14. vi. 1892 (Lieut.-Colonel Yerbury).

## Genus Stomoxys, Geoffr.

## Stomoxys limbata, sp. n.

$0^{\pi}$. -Length ( 3 specimens) 4.8 to 5.5 mm . width of head $1 \cdot 6$ to 2 mm . : willh of front at vertex 0.4 mm ; length of wing 4.6 to $5 \cdot 25 \mathrm{~mm}$.
simoke-freey: fuce and sides of front liright yellowishsilvery, firmt narrore: dussmm of thorus with usual clovebrom'n longitudinal stripes, udmedien stripes narrone and wide "pertt ; dorsmin of abdomen wilh deep, clure-hrourn or blackish tronsecrse band on hind border of earh of first three segments; wings with a brounish tinge: fomora durk cloce-biomen, their eatirme tips and lase of himed thina ochrucears-bu!lf, froml and middle libice und tursi mummy-lirourn, hind tarsi and himd tibia except base sepia-coloured.

Head: frontal stripe clore-brown, slightly constricted in middle ; oceiput dark grey, latero-penterior orbits grey : palpi buff: antenme greyish brown, tip of second and exficme base of third joint och raceous-rufous. Thorace: admedian stripes on dorsum extending from front margin to a point rather less than half-way betweeu transwerse suture and prascutellar groove, onter stripes much broader and conspichously interrupted by transerse suture; mesopleural hristles fairly stout. Abdomen: dark band on dorsum of second segment occupying more than half the segment, bands on first and third segments narrower; sccond and third segments usually tith a narrow median clote-brown stripe, which on third segment may be ohsolete. Squamce strongly tinged with brown. Halteres buff.

India: Calcutta, 16. vi. 1907 : additional specimens from Port Caming, Lower Bengal, 21. rii. 190t (Di. N. Armandale), and Calcutta, 20. viii. 1907, are in the collection of the Indian Museum.

What appears to be the female of this species may be characterized as follows:-
q. - Length (3 specimens) 5.5 mm . ; width of head 1.8 to 2 mm . ; width of front at vertex just over 0.5 mm .; length of wing 4.75 to 5.5 mm .

Apart from usual sexual differences ayreeing essentially with ס, eacept that dark markinigs on dorsum of thorax and abdomen are paler (olive-brown instead of clove-brown or blackish), that the uings although brormish are less moticeably infuscated, that the syuamce are puler (whitish or yellowish "hite), and that the fiont and middle tibice are also lirighter in have.

Head: face silvery, sides of front light smoke-grey, duller than in $\delta$; frontal stripe clove-brown, its sides somewhat convex below middle; palpi and untennce as in $\mathrm{J}^{\circ}$. Abdo$m e n:$ median longitudinal stripe on dorsum broader and less sharply defined than in $\delta$. Leys: tarsi and hind tibice except base mummy-brown.

India and Ceylon: type from Sylhet, Assam, India, 11. ii. 1905 (Major E. A. W. Hull, 1.iI.S.) ; a second specimen from same locality and collector, 31. i. 1905, received for determinaion from Indian Museum, Calcutta; a third specimen, from Peradeniya, Ceylon, 2:. v. 189:2 (Lt.-Col. Yerbury).

Stomoxys limbata is closely allied to St. nigra, Macq., but is distinguished by the front in the $\sigma$ being somewhat narrower, with the frontal stripe slightly constricted in the middle, instead of having its sides parallel, and in the of by the front and middle tibie being mainly ochraceous instead of for the most part clove-brown or blackish.

## Stomoxys pusilla, sp. n.

む. - Length ( 2 specimens) $4 \because 2$ to 45 mm . ; width of hear 1.4 to 1.5 mm . ; width of front at vertex 0.4 mm ; leugth of wing 4.25 to 4.5 mm .

Dorsum of thorax monse-grey or yellowish grey, with usual clove-broun lomgitudinal stripes ; dorsum of abrlomen olivegrey, first seyment, except a small ill-drfined arca in centre (not reaching hind maryin), sccond segment, either eutirely or rith eacception of extreme fiont marigin, and a median lonyitudinal stripe and fairly decep posterior transserse band on third segment clove-brourn; sides of fiont and sides of face, when rievod from above, liyht maize-yellow: wings brouenish; fimora clore-brown, front and midelle tibiee and tarsi and extreme tips of fromt und middle femorra bulf, hind tibier und tarsi light mummy-brown, base of tibice paler.

Head: occiput grey ; front fairly narrow, frontal stripe clove-brown, constricted in middle, sides of front conspicnous; palpi buff; antennce dark brown or mummyl, rown, tip of second and extreme lase of third joint ochrareons rufons. Thorene : admedian stripes on dersum moderately wide apart, their width about half that of outer stripes at widest portion of latter; length of admedian stripes as in foregoing species; pleurie mouse-grey, mesopleure dark brown, at any rate when viewed at certain angles. Aldomen: median longitudinal stripe an dorsum of third segment fairly broad. Sipuance and halleres as in foregoing species.
hidia: type and one other specimen from Allahabad, [̈nited Provinces, October 190J (F. 1I. Honlett).

Stomuatys pusilla differs from st. limbuta in its smaller size, in the yellower colour of the sides of the front and face, in the dorsum of the second adodominal segment being entirely clove-brown in practically so, instead of having a clovebrown prosterior transverse band and median longitudinal surpe, and in the pale tibite and tarsi of the front and middle legs.

## Stomoxys pulla, sp. n.

б. -Length (2 specimens) $1: 2$ to 4.4 mm ; width of head 1 ( $\%$ to 1.8 mm . ; width of front at vertex 0.4 mm ; length of wing $4 \cdot 2$ to $4 \cdot 6 \mathrm{~mm}$.

Iit! duck sipucies: when vioural from above hodly ajpectiong almust miformbly clove-brounn, eatreme fromt margin of thorow monse-grey, with commencement of usual clove-brown lomyitudinal stripes; when ubdomen is riewed from behind, at a very low anyle, terminal seyment appears olve-yrey, while secomd and third segments may appocar more or less mouse-grey, with choce-brourn transserse blutches, and perlaijs a truce of " narive median longitudinal stripe ; front narrour, occupied jor most part by frontal stripe, sides of front not noticeable except unteriorly; winys brownish; legs cloze-broun, tibice ochraceousbuff at extreme base, first juint of front tarsus frimged un inside with a row of hairs of equal length, claws black.

Head: sides of frout auteriorly yellowish, face silvery, upper portion of occiput clore-brown, basi-occipital region and latero-posterior orbits grey ; frontal stripe clove-brown, slightly or scarcely constricted in middle; palpi buff; antenne uniformly clove-brown. Thorax : pleuræ dark grey, menopleure clove-brown above; lower portion of lateral margins of scutellum, in front of apex, grey. Abdomen:

Wackish hair on dorsum of fourth segment long and fine. Squame: thoracal squama brown. Halteres buff.

India: type and one other specimen from Mussonrie, Einited Prorinces, September 1906 (F. M. Iowlett).

This is a very distinct species, which, while resembline the forcegring in size, is at once distinguishable by the dusky culoration of the body and legs, by the sides of the front being scarcely risible except anteriorly, and by the remarkable row ol hairs on the inside of the first joint of the front tarsus. Owing to the latter character St. pulla $\delta$ presents some slight approximation to the $\delta$ of the African St. omeyn, Newst, in whech, however, the row of hairs on the inside of The front tar-as extends to the end of the second joint, while the hairs themelves are much longer and conspicnously curled.

## Musctive.

## Philematomyia*, gen. nov.

「ireyish flies, not umlike Nusca domestica, Limn., in general appurance, but distimypishable at once owiny to the remarhathle piobuscis.-Frout in of narrons, its wilth in centre being from. one-clerenth to one-fifteenth of totul width of heod ; width of fromt in of at certex one-third of total wdith of head ; proximal frition of probuscis (mentum) a stromyly swollen chitimous bulb, "isial purtion srift and fleshy, firlled buck under distul end of' l. If when not in use, but when in "se extended, its terminal orction consisting if a "tubular eitension," which is protruled from lectucen the la'polla, and is suromeded at the shistal eetrimity with a circlet of stout chitinous teeth; venation generally as in Musca domestica.

Head: arista feathered as in Musca domesticu; palji slender, cylindrical, slightly thickened at tips; proboscis when not in use can be entirely retracted within buceal cavity, so as to be intisible when head is riewed in profile, but, in dead specimens at any rate, more usualiy protrudes, projecting downwards at an angle of about $45^{-c}$; the bulb is p lished and ljears scattered han's. When the fle-hy distal prestion is reflexed beneath distal end of bulb, the extremity of the proboscis has a pointed appearance ; the fleshy portion, hive the bulb, bears fine hairs; when retlexed, the fleshy portion ends in the lalellu, which therefore come to lie hetween the pointed tip of the proboscis and the rounded ba, of the bult), and, when the proboscis in this condition is

[^48]seen in profile, look like a fleshy pad lying on the under side of the bulb just beyond the middle; when the proboscis is in use the fleshy portion is extended until it lies more or less in a line with the bull), and the "tubular extension" (which, in a fly of normal size, is approximately 0.5 mm . in length) is protruded from between the inmer surfaces of the labella, of which surfaces it forms a prolongation ; the extension is supported internally by a pair of stout, black, chitinous rods, which are visible through the semitransparent wall, and have their proximal extremities situate between the tips of the

Philcmatomyia insignis, sp. n.
Fig. I--ITrad of of in profile, showing probuscis as it aplears when not in use $(\times 25)$.
labella; the wall of the extension shows humerous parallel trachear; in dried specimens, at any rate, the discal extremity of the extension appears to consist of a thickened fleshy ring, armed with pale yellowish teeth in addlition to the circlet of stout, black, pointed, chitinous teeth, which are situate ol its inner margin.

Thoracic bristles:-Humeral, 3 (in ס sometimes 4). Posi-humeral, 1. Notopleural, ㄹ. Prcesutnral, 1. Supnoaalar, 2. Intratalar, 1. Post-alar. 3. Dorso-central, 4 or 5 (the large and conspicnous bristles alme included-2 or 3 in
front of, 2 behind suture). Inner durso-central, 1. S'chtellar, 4 (l prehasal, l hasal, 1 discal, 1 apical). Mesopleural, normally 6 (space between uppermost two greater than that between any other two). Slernoplerient, $1: ?$.

IV̈nys: venation as in Musca domestica, Linn., except that the terminal portion of the fourth longitudinal vein, after

Philamatomyia insignis, sp. n.
Fig. II.-Proboscis of 9 , with "tubular extension" not quite fully protruded ( $\times$ about 70).
Fir. III.-Proboscis of $\sigma^{*}$, with tabular extension fully protruded. showing circlet of stout, black, chitinous teeth ( $x$ about 70 ).
the bend, is straighter and less incurred, and that the posterior transserse vein is more simuous; opening of first posterior cell as in Musca domestica.

Typical species, Philamatomyia insignis, sp. n.
The genus Philematomyia, of which but a single very widely distributed species has yet been obscrect, consists of
hlood-sucking flies, which form a remarkable connectinglink between the ordinary non-biting Muscinse and the Stomosydinæ. In the case of species belonging to the latter group the slender chitinized proboscis (labium) is thrust bodily into the skin of the animal or human being on which the fly is feeding, and so forms a piercing organ. In Philematomyia, however, there is no actual piercing organ, since the fleshy termination of the proboscis is obvionsly incapable of being thrust into the skin of a vertebrate, and the fly feeds by cutting through the epidermis of its victin by means of the powerful teeth at the end of the tubular extension, and then sucking up the blood in the ordinary way.

Philamatomyia insignis, sp. n.
of of.-Length, d ( 17 specimens) 3 to 5.8 mm ., f (25) specimens) 4 to 6.5 m .n. ; width of head, ठ 1.3 to $2 \cdot 2 \mathrm{~mm}$., of 1.4 to 2.25 mm . ; width of front in centre, d 0.08 to 0.2 mm ., of 0.6 to just over 1 mm . ; length of wing. 万 3 to 5.5 mm ., \& 3.2 to 5.6 mm .

Smoke-grey to isabelline grey, or yellowish grey; dorsum of thorax with four dark longitudinal stripes, broader and clovebrown or blachish in $\delta$, narrouer and darli grey or broumish in \&, $\delta$ often with an additional, broad, median stripe, mist distinct in front and belind; dorsum of abdomen with a transversely clongate dark blotch on first segment, not reaching hind margin, and a small clove-brourn median triangle at brise of second and third segments, in some specimens also with a similar but smaller and usually lighter mark at lase of forith segment : all hair and bristles on head, body, and leys black: palpi ochraceous-butf; winys hyaline or with a slight ochiruceous tinye, veins in mroximal hulf buff or ochruceous-bu!ff; legs black, femora greyish pollinose.

Head: posterior orbits, front, and face yellowish grey or silvery grey, occiput dark gree; frontal stripe clove-brown in $\delta$, greyish clove-brown in $f$, in $\delta$ extremely narrow, often reduced to a mere line above, but expanding somewhat below, in of broader though still narrow, its sides nearly straight, and its width scarcely exceeding and often distinctly less than that of sides of front; upper inner margins of epes converging slightly at vertex in $\circ$; bulb of proboscis shining clove-brown ; antennce dark brown, tip of second joint narrowly ferruginous, third joint greyish, arista and its hairs dark brown, tip of arista cinnamon-rufons. Thorax : outer dark stripes on dorsum not reaching front margin, narrowly interrupted on transwerse suture, and behind scarcely ex-
tending to post-alar calli, admedian stripes extending from frout margin to ahout one-third of distance from transwerse suture to presutural furrow, median stripe, when present, usually pointed anteriorly and not extending to front margin, but behind broad and reaching presutural furrow; below outer dorval stripe on each side, especially in $\delta$, there is often an additional dark longitudinal stripe; in of specimens in certain lights a broad dark stripe can be seen rumming from hind margin of humeral callus, across upper portion of mesopleura, to mesopleural suture. Abdomen: venter grey, median scutes darker.
ludia, Ceylon, Sokotra, Cyprus, Scucgal, and Congo Free State: types of $\delta$ and $q$ and four other specimens from India (Bombuy Nutural History Suciety) ; ? of of from ('alcutta, India, 23. vii. 1907, "on draught bullocks, burvowing into the hair" (received from the Indian MIuseum, C'alcutta); $1 \delta^{\top}, 1 \quad$ P, from Mussooric, United Provinces, India, Sept. 1906, and 1 \& from Allahabad, United Provinces, Indin, 11. x. 190.5 (F. M. Horlett) ; 2 己 む, 5 \& $\ddagger$, from Bentota, Ceylon, 13. vi. 1891 (Lt.-Col. Yerbiery) ; 1 of from Dankotura, Ceylon, 1899 ( C. G. Rodrigo) ; 2 б 3 from Hadibu Plain and Dahamis, Sokotra, 12 \& 19. xii. 1898 (W. R. O. Grant) ; 3 б $\boldsymbol{\delta}$, 12 ㄱ ㅇ, from Larnaca, Cyprus, 4. viii. 1908 (Dr. G. A. Williamson) ; 3 ठ $\delta^{\pi}, 1$ ¢, from St. Louis, Senegal, W. Africa, 16. v. 1903, "feeding on donkeys on race-course" (the late Dr. H. E. Dutton and Dr. J. L. Tordd); 1 ot 1 of from the Congo Frec State, 1903 (Dis. Dutton, Todd, and Christy). Writing from Larnaca, Cyprus, on Octoher 23,1908 , with reference to this species, 11r. G. A. Williamson remarked :-" That this is a biting fly my ankles have on many occasions borne evidence, and I notice that horses can stand its bite very little, becoming much more restive than with the Hippobosca [H. equina, Limn.], which seems to cause them little inconvenience."
XXXVIII.-On some new Stencosaurs from the Octort Clay of Peterborough. By C. W. Andritws, D.Se., F.I...' (British Museum, Natural History).

> [Plates VIII. \& IX.]

The splendid collection of reptilian remains obtained by Mr. A. N. Leeds, F.G.S., from the Oxford Clay in the neighbourhood of Peterborongh, includes the skeletons of
many marine croondiles. The commonest of these are species of Metriorlynchus, but Stenessutus and Dacosturne are alsu represented. In the present papser it is preproel to give a brief account of the species of stencosturus inchled in the collection. One of these, Steneosumrus enturdsi, has alrealy been described in detail hy E. Desmechamps from specimens from the Oxford Clay of Vaches Noires, Normanly. In addition to this, which need not be further moticed, there appear to be at least four other species, nom of which seem to agree at all closely with previonsly described forms and they will therefore receive new names.

## Steneosaurus.

This genus is here regarded as it was emended by Deslongchamps and afterwards adopitnd by Ledekker and whers. Ladekker's Anfinition given in the 'I'atalogne of Fossil Reptiles in the British Musemm,'pt. i. (1595), p. 16R, is here followed, all the species described falliner within it, with the possible exception of that named $S$. obinsidens, which may eventually have to be referred to a new genus.

## Steneosaurus leedsi, sp. n. (Pl. VIII. fig. 1.)

Professor Bigot $\dagger$ has recently described a Steneosaur with a very long and slender snout from the Callovian of Calvades, and for it he has adopted the name Steneosaurus roissyi, a species originally established by E. Deslongchamps $\ddagger$ on the evidence of some small fragments of a mandible from the Oxford Clay of Vaches Noires. Mr. Leeds has poiated out to me that there can be little douldt that the type specimens are portions of the jaw of a Metriorhynchus, so that the name is not that of Stencosaur at all. In the Leeds collection is a very fine skull and mandible (R. 3320), the latter closely resembling the one figured by Bigot ; and these specimens I propose to make the types of a species $S$. leedsi, to which Bigot's specimen no doubt is likewise referable.

The chief peculiarities of this species are the great length and slenderness of the flattened snout. Thus the length of the skull (from the occipital condlyle to the tip of the nose, allowing for 1 or 2 centimetres broken away) is 81 cm ., while that of the pre-orbital region is 595 cm ., or about $73 \frac{1}{2}$

[^49]per cent. of the whole length. In the case of the mandible the total length is 8.9 cm. ; that of the symphrial region is 52 cm ., or about 58 per cent. In the mandible fignted by Bigot the total lenath is 100 cm ., the length of the symphysis is 55 cm . Both the proportions of the length of preorbital portion of the rostrum to the whole length of the skull and of the symphysis to the whole man lible are greater than in other species. In S. megistorhynchus, which seems to be the next most elongated form, the symphysial portion of the mandible is only 50 per cent. of the whole. Another characteristic of $S$. leedsi is the larse number of tecth present, there being $45-46$ on each side of the upper jaw and $43-44$ in the lower.

In the skull the temporal fosse are very large and are much longer than broad (length 12 cm ., breadth $7 \cdot 3 \mathrm{~cm}$.). The orbits are rather large and are oval in outline; they look upwards and outwarls, as in other members of the genus. The combined frontals terminate anteriorly in an acute angle, consilerably in front of the anterior border of the orbit; their upper surface is ormamented by a few scattered pits only. The nasals extend back to about the anterior thir of the orbit, but their limit in front camot be determined with certainty. The anterior part of the suout was greatly flattened from above downward: the enl, formed by the premasillæ, is somewhat expander. The facial processes of the premaxilla are short and terminate in a blunt point opposite the interval between the second and third masillary teeth. (On the palate the maxillo-premaxillary suture is nearly straight and is at right angles to the long axis of the skull. The palatal surface is flat in the premaxillary region, but behind this it is concave from side to side, the alveolar border forming a somewhat sharply raised rim: the conver upper surface of the symphysial region of the mandible fits closely into the concavity of the palate. The upper teeth are $45-46$ in number. The two posterior premaxillary teeth are enlarged and are separated by an interval nealy equal to the diameter of their alveoli. 'The maxillary teeih are nearly equal in size throughout the series; they are directed downwards and forwards. The individual teeth are sle der and sharp; they are slightly compressed at the extreme tip and the enamel is markel by a series of fine longitudinal ridges. The symphysial portion of the mandihle is slightly exp anded anteniorly, especially between the enlarged third and fourth teeth; its upper surface in this region is nearly flat, but behind it

Ann. \& Mag. N. Hist. Ser. 8. Tol. iii. 21
becomes convex from side to side, rising considerably above the alveolar borders. The ventral surface is aently convex from side to side. The splenials extend forward in the symphysis to the 24 th tooth.

The dimensions of the type skull and mandibles (R. 3320) of Steneosaurus leedsi are :-
Skull. ..... cm.
Total length ..... 81
Length in front of orbit ..... 59
Width between outer angles of the quadrates ..... 18
Length of temporal fossse (inner side) ..... 12
Width ..... $7 \cdot 3$
" of frontals between orbits ..... 3.9
,, opposite anterior border of orbit ..... $10 \%$
" of middle of snout ..... $4 \cdot 3$
," behind premaxillary expansion ..... $2 \cdot 9$
" of premaxillary expansion ..... $3 \cdot 8$
Mandible.
Total length ..... $8 ?$
Length of svmphysial portion ..... 52
Width at hinder end of symphysis ..... $7 \cdot 3$
$n$ at narrowest point behind anterior expansion ..... $2 \cdot 2$
Steneosaurus nasutus, sp. n. (Pl. 1X. fig. 1.)

The type specimen upon which this species is founded is a nearly complete but somewhat crushed skull and mandible. In some respects the skull shows an approximation to the Teleosaur type, particulanly in the relative shortness of the temporal tusise in proportion to their width, and the position of the orbits, which appear to have looked more directly forwand than in the other species of the genus. The frontal: between the orbits are much sculptured with a number of pits and strong rugosities; the form of their anterior end camot be determined. 'The upper surface of the triangular area of the parietals at the hinder end of the sagittal crest bears sculpture like the frontals. The rostrum is very long; in front of the orbit the narrowing of the skull is rapid for a short distance, then the sides of the slender rostrum become nearly parallel, as it narrows very slightly till just behind the premaxillary expansion, which seems to have been of considerable width. The two posterior teeth in the premaxilla are enlarged and closely set together. The maxillary teeth are nearly equal in size throughout the series: they seem to have been directed forwards and downwards; their crowns are comparatively
slender, sharp-pointed, and the enamel is marlsel by a series of very fine longitudinal ridges with a rather stronger and more continuous ridge on the outer side.

The mandible is slender and compressed vertically. The palatal surface appears to have been somewhat convex. The ventral surface is marked by an ornamentation of irregular longitudinal ridges. There is a slight anterior expansion and the thind and fourth teeth are enlarged; there are 42 tecth on either side and their structure is similar to that of the upper teeth. The splenial extends into the symphysis as far as the twenty-second tooth. The posterior (ventral) limit of the symphysis is opposite the thirty-seventh tooth.

This species approaches $S$. leedsi in the length of its snout, the preorbital portion of which is about 73 per cent. of the whole length of the skull in both species; in the next species, S. durobrivensis, it is only about 61 per cent. In the number of teeth it also resembles $S$. leedsi and differs from $S$. durubrivensis, in which the number is smaller. On the other hand, it is sharply distingnished from $S$. leedsi by the shorter tompmal fosser, the position of the orbits and the strong sculpturing of the frontal bones; and the first two of the characters at least separate it from S. inturnedius, S. edwardsi, and S. heberth, from all of which it differs further in the possession of a greater number of teeth.

The dimensions of the type skull and mandible of Steneosaurus nasutus are :-
Skull. ..... cm.
Total length ..... 100
Length in front of orbits ..... 73
Wiath between outer angles of the quadrates ..... 25
Length of temporal fossæ (inner side) ..... 14
Width " " ..... $10 \cdot 5$
" of frontals between the orbits ..... 6
" at anterior border of orbit ..... 16.5
", of middle of snout ..... $6 \cdot 3$
behind premaxillary expansion ..... $4 \%$
" of premaxillary expansion ..... $7 \cdot 3$
Mandible.
Total length ..... 110
Length of symphysial portion ..... 62
Width at hinder end of symphysis ..... 11.6
,, immediately bebind anterior expansion ..... 4.2

Owing to the crushing that the specimens have undergone, many of the above measurements can be regarded as approximate only.

## Steneosaurus durobrivensis, sp. n. (Pl. VIII. fig. 2.)

A third species of Steneosaurus which occurs in the Leeds Collection has a considerably shorter rostrum than those just described, but at the same time it is longer than in 'S. edwardsi, which is found in the same beds. It differs' from the contemporary $S$. heberti in possessing only 33 teeth in the upper jaw instead of $39-40$ as in that species, and the mandihular symphysis is relatively longer. The points of difference from S. intermedius are the same.

The type spacimen (Leeds Coll. 18) upon which it is proposed to fomed this species is a beautifully preserved and nearly complete skelcton, including:-skull, mandible; 9 cerrical, 14 dorsal, 2 sacral, and 39 caudal vertebre; many ribs of both cervical and dorsal regions, several chevrons; shoulder-girdle, humeri, (?) radius and ulna; pelvic girdle and most of the bones of the hind limb; many scutes from all regions of the body. In the present paper only the skull and mandible will be briefly described, the complete account being left for the 'Descriptive Catalogue of the Marine Reptiles of the Oxford Clay' now in preparation.

In the skull the temporal fosse are very large and about twice as long as wide. They are separated by a high and very thin sagittal crest. The oibits are relatively rather smaller than in S. leedsi and are more widely separated. The frontals are almost smooth ; their anterior angle is a little in front of the orbit ; the form of their anterior border will be best understood from the figure (Pl. VIII. fig. 2), and differs widely from that of the frontals in $S$. leerlsi and $S$. heberti, but approaches that figured by Bigot in S. intermedius. The nasals terminate anteriorly opposite the 16 th maxillary tooth, counting from before backwards. In front of the orbit the rostrum narrows rather quickly at first, then very gradually to the premaxillary region, which is only a little expanded. The suture between the premaxilla and maxilla is convex posteriorly on the upper surface, the facial processes of the premaxilla extending back to the level of the second maxillary tooth. On the palate the suture between the two bones runs forward after crossing the alveolar border, and an anterior prolongation of the maxillæ is thus interposed between the small palatal plates of the premaxillæ. The median suture between these latter is interrupted by a foramen situated at the level of the socket of the third tooth.

The upper teetli are about thirty-four in number. The premaxillæ bear four each, of which the first two are small, crowded together, and directed forward ; the third and fourth are large and their alveoli separated by four or five millimetres only. Behind these there is a short, concave, edentulous space; then follows the series of 29-30 maxillary teeth, which are relatively large, and are separated by intervals less than the diameter of their alveoli. 'The teeth are directed downward and a little forward.

The rami of the mandible are stout; they pass into the symphysial region by a gentle curve. The symphysis reaches back to the 25 th tooth and the splenials extend forward in it to the level of the 17 th tooth. Both the upper and ventral surfaces of the symphysis are nearly flat; there is a slight expansion between the enlarged third and fourth teeth; at the anterior end the line of junction of the two rami is marked by a deep median notch.

The first two lower teeth were small and directed nearly straight forward ; the third and fourth are the largest in the jaw and are closely crowded together. Behind these there is a short diastema ; then comes a series of about 27 teeth, a few of those in the front and close to the back being somewhat smaller than the others. 'They appear to have been directed upward and a little forward.

No good specimen of the teeth, either upper or lower, has been seen, all having either fallen from their sockets or been broken off short. Judging from some of the replacing germs, the crown would appear to have been blunter than those of the species described above, but muci less so than is the case in the next species.

The dimensions of the skull and mandible in the type specimen of Steneosaurus durobrivensis are:-
Skull. ..... cm.
Total length ..... 74
Length in front of orbit ..... 45
Width between outer angles of quadrate ..... 24 䊉
Length of temporal fossæ (inner side) ..... 18
Width ..... 8.8
" of frontals between orbits ..... $5 \cdot 4$
", of middle of snout ..... 6.4
", behind premaxillary expansion ..... $4 \cdot 8$
" of premaxillary expansion ..... $5 \cdot 7$

[^50]
## Mandible.

$$
\text { Total length . ........................................ . } 85
$$

Length of symphysial region ..... 37.5
Width at hinder end of symphysis ..... $10 \cdot 2$
," at narrowest point behind anterior expansion. ..... 3.8

Sleneosaurus obtusidens, sp. n. (Pl. IX. fig. 2.)
One of the most important of the skeletons collectel by Mir. Le ds is that of a very laree and massively built croco lile, of which we poos ss the skull, mandible, numerons vertebre and ribe, some bones of both the peetomal and pelvic girdles and of the fine and hind limbs, together with some scutes. 'These specimens ( R .31 C 8 ) are the typ of the present species.

The skull differs from that of the other Steneosaurs in having a thicker and more massive rostrum and teeth with thick blont-pointed crowns. As in the last species, the temporal forse are very large and about twice as long as broad. The orbite are large and oval. The frontals seem to have terminated anteriorly in a blunt point about on a level with the front border of the orbit; their surface is ornamented by a number of chbecure ridges bartiating from the contre of the mated bones. The arrangement of the masals and lachrymals camot be made ont, owing to the crushing that that reuion has undergone. There was a small slit-like antorbital furamen, about 7 cm . in front of the orbit. In front of the orbits the roitrum narrows very gently to a point alont 16 cm . behind its anterion end, where it is conly- 6.2 cm . wide; the premaxillary region is expanded and the facial processes of the fremaxille terminate posterionly in a blunt puint. The nasal opening is transersely oval, the anterior border being interrupted by a prominence occurring at the print of union of the two bones. The rostrum, as a whole, is stout and its upper surface is strongly arched from side to side; the anterior end seems to have been bent a little upwards. The total numlier of teeth in the upper jaw camot be made out, but it can be seen that in the premaxilla there were four, of which the two anterior are small and crowded together, so that the second is almost behind the first. The third and fourth are much enlarged.

In this skull the length of the proorlital region is about 61 per cent. of the whole; in S.leedsi and S. nasutus the proportion is about 73 per cent. ; but in $S$. durobrivensis it is much the same as in the present species, which, however, differs in the more gradual narrowing of the rostrum.

The mandible is very massively constructed. The symphysial region, which occupies about 42 per cent, of the total length, is flattened ventrally and has a considerable anterior expansion, which is greatest at the sockets of the third and fourth teeth.

The lower teeth are about 28 in number. The first two are small, then follow two large teeth closely crowded together. Behind these is a rather small tooth, and behind this point the rest increase in size till near the hinder end of the series. The most remarkable character of this dentition is that about half the mandibular teeth bite into deep pit-like sockets in the maxilla; the outer walls of these pits form slight prominesces on the alveolar ellges of the maxilla. If this peculiarity of the dentition is normal it would probably justify the establishment of a new genus for the reception of this species, but there is some doubt whether it may not be the result of great pressure, which has driven the points of the lower teeth into the maxilla, while the bone was in the clay in a semi-plastic condition.

The individual teeth are thick, circular in section, and have blunt points; the enamel of the crown is raised into a number of fine longitudinal ridges of varying length; in some of the teeth two or three ridges on opposite sides are more strongly marked than the others and are continuous from base to tip of the crown.

This crocodile seems to have been a very powerfully built animal, with jaws and tecth of greater strength than in the other Steneosaurs. The hind limb was very long, the femur alone measuring 45 cm . in length. A detailed account of the skull and skeleton will be given in the Catalogue above referred to.

The approximate measurements of the type skull and mandible (R. 3168) of Steneosaurus obtusidens are:-
Skull. ..... cm.
Total length ..... 116
Preorbital length ..... 71
Width between outer angles of quadrates ..... $37 \cdot 5$
Length of temporal fossæ (inner side) ..... 33
Width
(?) 14
" of frontals between orbits ..... 8.5
" of middle of snout ..... 9
", at narrowest point behind premaxillary expansion ..... $7 \cdot 3$
, of premaxillary expansion ..... 9.5
Mandible.
Total length ..... 137
Length of symphysial region ..... 58
Width at hinder end of symphysis ..... 14
,, at narrowest point behind anterior expansion ..... 6.2

## XXXIX.-The Gemus Encrinus. By Austin IIobart Clark, of the United States Bureau of Fisheries.

Mr. F. A. Bather in 1898 ('Natural Science,' xii. p. 24.5) attempted to unravel the snarl in which the generic names of the recent (and fossil) Pentacrinitile have hecome enmeshed, thanks to the nomenclatorial carelessuess of cortain of the writers on the sulject of the Cimoidea. Passing over the fact that Bulanocrinus is not available for any genus of Pentacrinitilæ, that Metucrinus was first diagnosed in 1882 (Bull. Mus. Cimp. Zool. s. p. 167), and that Isocrinus was first propnsed in 1836 (L. Agasiz, Mém. de S.re. de Šici. Nat. de Nenclîtel, i. p. 195, trpe Inocrinites pindulus, de (sic) Meyer, $18: 55$, nomen nulum, $=$ Isocrinus pendis'us, von Meyer, 1837), we come to a consideration of the cenus Encrimus. Mr. Bather ascribes Encrimus to Schulze, 1760; but Schulze was not binomial, as a glance at his work suffices to show; moreover, if he were, why does not Mr. Bather use his genera Decacnimos, Polyactinis, and Triscredecacnimos instead of the later Antedon and Actinometra?

Encrinus was first proposed binomially by Blumenbach in 1779 ('Handbuch der Naturgeschichte,' (Göttingen, p. 435), and contained three species, all recent-(1) asteria (Isis asteria, Limmus, 1766, based on Guettard), (2) mylii (a pennatulid of the genus Umbellularia), and (3) boltemii (an ascidian of the genus Boltenia).

In 1788 Blumenbach ('Handbuch der Naturgeschichte,' Göttingen, p. 503) again gives Encrinus, with the three species, (1) asteria (as before), (2) radiatus (=Vorticellin encrinus, Limreus), and (3) ouifer ( = Vorticella "ouifer," Limmus). Thus the genus Eincrinus, as understood by Blumenbach in 1779 and 17SS, contained the same three species, though two of them were included under different names.

Lamarck in 1801 ('Syst. des Animaux sans vertèbres,' p. 379) appears to have been the fist reviser of the genus. He included in it two species, (1) caput-medusre ( $=$ Isis asteria, Linnæus, $=$ Encrinus asteria, Blumenbach) and (2) the fossil Lincrinus liliformis. The latter is excluded from all claims as the type of Encrinus by the fact that it did not appear in the genus as originally proposed by Blumenbach. Furthermore, Lamarck removed from all consideration the second species, mylii or radiatus, by establishing for it the new genus Umbellularia (p.58(1). According to the views of Lamarck, asteria was the only species of the original Encrinus which could be retained in that genus, as restricted by him.

In 180.4 Blumenbach ('Abbildungen naturhistorische Gegenstände,' p. 60, pl. lx.) gives the name Encrinites fossilis to Lamarck's second species, E. liliaformis, and also (p.70, pl. Ixx.) gives the name Pentacrinites fossilis to the species subsequently called Pentacrinus briareus by J. S. Miller. Neither of these names can have any influence on the selection of the type of Encrinus, as neither species was included in the original genus.

In 1816 Lamarck repeats his original disposition of the genus Encrinus, and in the same year Savigny (' Mém. sur les Animaux sans vertèbres,' $2^{e}$ partie, p. 140) finally removes the third species of Blumenbach's original genus, boltenii or ouifer, making it the type of his new genus Boltenia. This makes it clear that asteria alone remains as the type of Encrinus; summarized, the elimination is as follows:-

Encrinus, Blumenbach, 1779.
(1) asteria.
(2) mylii (or radiatus) (type of Umbellularia, Lamarck, 1801).
(3) boltenii (or ouifer) (type of Boltenia, Savigny, 1816).

It may, perhaps, be mentioned that Oken's use of Fincrinus ('Lehrbuch der Naturgeschichte,' 1815, iii. p. 110) for Blumenbach's secont species only does not enter into the question at all, for that species had, fonteen years before, become the type of Lamarck's Umbellularia.

Since the type of Encrinus is the Isis as'eria of Linneus, this involves considerable change in the nomenclature of the recent stalked Crinoids. The specivs of Meforinus, Eudorocrinus, and Hypalocrinus remain as previously understood (see Proc. Biol. Soc. Washington, axi. H1, 151, 152) ; the other species of the recent Pentacinitilk, astreia, decorus, and blakei, falling into two groups which camot be separated more than subgenerically, must be treated as follows:-

$$
\text { Genus Encrinus, Blumenbach, } 1779 .
$$

(Genotype.-Isis asteria, Linnæus, 1766.)

## Subgenus Encrinus, Blumenbach.

Encrinus (Encrinus) asteria (Linnæus).
Subgenus Isocrinus, L. Agassiz, 1836.
(Genotype.-Isocrinus pendulus, von Meyer, 1837.)
Encrinus (Isocrinus) blakei (P. H. Carpenter).
Encrinus (Isocrinus) decorus (Wyville Thomson).
XL. -Note on a rare Plumularion Hydroid, Cladocarpus formosus. By James Ritchie, M.A., B.Sc., Natural History Departmeut, the Royal N'cottish Museum.
Is 1874 Allman described, under the name Cladocarpus formosus, several hydroid specimens obtained by the
'Porcupine' in the deep water to the south of the Faroe Islands \%. Four colonies of this rare and beautiful species occur amongst material collected by Dr. A. Bowman, of the North Sea International Investigations, during the autumn of 1908 , and handed to me for examination through the kindness of Prof. D'Arcy W. 'Thompson, C.B. 'They were dredged in the Faroe Channel (Station 19 a, lat. $60^{\circ} 36^{\prime} \mathrm{N}$., long. $4^{\circ} 46^{\prime} \mathrm{W}$.) at a depth of 1030 metres, in the immediate neighburhood of the places from which the type specimens were obtained.

The colonies vary in height from 4 to 7.5 cm ., and in general agree with Allman's description, but as regards their minute structure these additions and corrections have to be made. The colonies are fascicled for the greater part of their length, but only the antelior tube is divided into internodes, upon each of which a single hydroclade is borne. Allman's figure (pl. Ixviii. fig. 1 a) errs in indicating that the hydroclades arise from different components of the fascicle. 'Ihe hydroclades are alternate and rest on short processes from the stem. The hydrotheca are deep and cylindrical, with a straight profile, an aperture lying at right angles to the long axis of the stem and in line with a hydrocladial node, and a margin bearing an anterior prominent tooth accompanied by a smaller tooth on each side. About five indefinite sinuations also occur on each lateral margin.

Within the hydrocladial internode are several well-defined ridges, five gencrally springing from behind the hydrotheca, and a number, varying from two to four, from its base. One or two shonter ridges project into the proximal portion of the internole from its anterior wall. A prominent septum, perforated by a minute opening, traverses the mesial nematophore near the point where it becomes free, and from about the same level a strong anterior intrathecal ridge extends horizontally backwards almost to the posterior wall of the hydrotheca. But there is no definite relationship between the position of the intrathecal ridge and that of the nematophore septum, the former being sometimes at exactly the same level as the latter, sometimes above it or below it. The mesial nematophore reaches haltway up the hydrotheca and is free for about half its length, except on the proximal internode of each hydroclade,

[^51]where it is much shorter and lies altogether free from the hydrotheca. Neither it nor the supracalycine nematophores are completely tubular; their margins are serrate. Each stem-internode bears three nematophores: one posterior, in the angle between internode-process and stem; the others anterior, one beside the stem-process, the other prosimal to it. The supporting tubes of the fascicle bear somewhat smaller nematophores, arranged on each tube in opposite pairs at regular intervals.

## Fig. 1.

Fig. 1. - Hydrotheca of Cladocarpus formosus. $\times 45$.
Fig. 2.-Hydrotheca of Cladocarpus crenatus, var. allmami. $\times 45$.
Viewed from the anterior the gonangia are obovate, but in lateral aspect the posterior wall is seen to be arched over the termino-lateral aperture (suggesting the overcurling tip of an oriental slipper), as in the case of C. ventricosus (Allman) \%.
"Cladocarpus formosus" of the 'Challenger' Report.Comparison of the characters above described with those of the solitary specimen obtained by the 'Challenger'-for the opportunity of examining which I am indebted to Mr. Edgar A. Smith, I.S.O., of the British Museum-shows that Allman's identification is mistaken. For the 'Challenger' specimen differs in lacking an intrathecal rilge, in possessing

* See Nutting, C. C., "American Hydroids: I. The Plumularidæ," Smithsonian Institution, Special Bulletin, Washington, 1900, pl. xxri. fig. 8 .
a more globular, less deep hydrotheca, with fewer and more definite marginal sinuations, in possessing two, seldom three, intemodal ridges, and in having the nematophore septum much nearer the base of the hydrotheca. The serrations on the margins of the nematophores, noticed by Billard ${ }^{*}$, are less distinct than in $C$. formosus, although, as there, the mesial nematophore on the proximal internode of each hydroclade lies below the hydrotheca and is free from it. The presence of this nematophore, the existence of which Allman denies, shows that the phylactogonium camot be "its morphological representative." On the hydroclade-bearing tube five nematophores usually accompany each hydroclade : one posterior, in the angle between internode-process and internode; one anterior, di-tal to the process, and three, almost in a whorl, proximal to it.

The 'Challenger' specimen I regard as a variety of Cladocarpus crenatus (Eewkes) described by Fewkes, in absence of the gonosome, as Aglaophenia crenata $\dagger$. Cladocarpus crenatus, var. allmani, nov. nom., differs from the type of the species in possessing only two instead of cight internodal ridges and in having three anterior teeth much more prominent than the lateral sinuations. The free portion of the mesial nematophore, too, is scoop-shaped, open towards the hydrotheca; but while Nutting describes that of C. crenct tus as "tubular" $\ddagger$, one of his figures ( $p$ l. xxiii. fig. 9, uppermost hydrotheca) represents it as open on the side facing inwards. This variety was obtained by the '('hallenger' in lat. $34^{\circ} 58^{\prime} \mathrm{N}$., long. $139^{\circ} 30^{\prime} \mathrm{E}$., in the neighbourhood of Yokohama.

The following measurements indicate, in mm., the sizes of the species discussed above :-

|  | C. formosus. | C. crenatus, <br> rar. allmani. |
| :--- | :---: | :---: |
| Stem internodes, length ........ | $0.91-0.98$ | Not discernible. |

[^52]The de-cription and figures of C'lndocurpus ermolatus, Levinsen*, recorded from Davis Stant, clearly indicate that That form is specifically identical with C', formosus, of which therefore Levinsen's name should be rearded as a synonym.
XLI.-Diagnosis of Soletellina dautz mbergi, sp. n., from New C'aledonia. By G. B. Sowerby, F.L.S.

Testa transverse subelongata, subrefuilateralis, crassinscula, purpurea, lineis atro-purpureis plerumque duplicat is radiata, epidermide olivacea induta; umbones minuti, fere conjuncti, rix clerati, leviter post medium locati ; margo dursalis anticus subelongatus, leviter convexus, mediocriter declivis; posticus brevior. rectinsculus, paulo declivis, rotunde angulatus: marge rentralis leviter arcuatus; latera antica rotundata, positiea conrexe fruncata. Ligamentum crassum, hreviter truncatum. P'agina interna purpurascens, atro-purpureo duplicatim radiata et postice suffusa: impressio musculari postica cordiformis; antica lingueformis: sinus pallii magnas, late oratus. Dentes cardinales valva dextrie duo: ralrae sini-tae una vel tres. Margo cardinalis antions tenuis, haud dentatus ; posticus crassus, lærigatus.
Long. (umbone ad marg. ventralem) 12, lat. 19 mm .

Soletellina dautzenbergi.

## Hab. New Caledonia.

I am indebted to the able and zealons concholugist Mr. Ph. Datzenberg for information concerning this species, which I have pleasure in naming after him.

[^53]
## PROCEEDINGS OF LEARNED SOCIETIES.

GEOLOGICAL SOCIETY.
January 13th, 1909.—Prof. W. J. Sollas, LL.D., Sc.D., F.R.S., President, in the Chair.

The following communication was read:-
'On the Genus Loxonema, with Descriptions of New Proterozoic Species.' By Mrs. Jane Longstaff (née Donald), F.L.S.
There is some confusion with regard to the trpe of the genus Loxonema, which has arisen from the confounding of the Silurian Teretica (?) simuosa of Sowerby with the Devonian form which Phillips called Loronema sinuosum. This matter is discussed, and the Author, following Liudström, Eoken, and Perner, takes L. sinuosum, Sowerby as the type, in the absence of sufficient reasons to the contrary. If this be done, the other two types mentioned by Phillips cannot remain in the genus, one belonging to the genus Macrocheilina and the other to $Z_{y y}$ gopleurct. This paper deals simply with Ordorician and Silurian species, therefore only a ferw subgenera a:e referred to-Rhabdostropha, Don., and S'tylonema, Perner.

The diagnosis of Loxonema is amended, and a note given as to the true range and the geographical distribution of the genus. Descriptions are given of Loxonema simuosum, Sow., of L. intumescens, Lindstr., and of L. striutissimum, Salt. Ms., and sis nerv species and one new rariety are described of this genus. Rlubdostropha pseudofasciatum, Don., and Rh. Grindrodi and a new species of this subgenus from Stoke Wold in the Lower Ludlow Beds are next described. This is followed by a description of two new species of the subgenus Stylonema-one from the Chair of Kildare and the second from Mulloch Hill. In conclusion, a new species of Hormotoma from the Llandeilo Flags of Builth Bridge is described.

## MISCELLANEOUS.

> On the Generic Name Chœrops, Riuppell. By J. Douglas Ogilby.

To the Editors of the Amnals and Magazine of Natural History.
Gextlemen,--Having been engaged lately on a recision of the bodian labrids of Queensland, the correct name of the genus commonly known as Choerops came duly up for consideration, with the result that I find that the two Bleekerian names Choirodon and

Cossyphories take precerience of Riiippell's name. The latest synonymy of the grnus is that given hy Jordan and Snyder (Proc. U.S. Nat. Mus. xxiv. 1902, p. 614); but if Bleeker is correct, as he donbtless is, in the statements (1tlas Ichth, i. [1]. xiii, $161, \& 162,15102$ ) that the name Cluivolon was propoed for these fi-hes more than sisteen rears ("il y a phus de 16 ans") before the pabliention of the work last quoteil. then the date-1-5;-iwn hy Jorlan and Guydur is manifestly incorrect, and should be altered to 14165 , while the reference to ri, ex, mplowis shaild ho, on Bleeker's own evidence (ibi, p. piii). 1-49 intend of $1-1 ; 1$. It is true that Blewker himsolf asserts that Chumors, liupulh, has priority orer his Chas, phorles ("étant postérieur à celui do. M. Rempell doit antoi etre supprimé"), hut the fucts, as we linorit them, fail to suppert this contention. It is quite possible that Ilecher was awate of Riippell's intention to name the genu: (hworn). and chaignet to athere lowally to that name, ret, through his neglow to cancel his own Cissi, hioilis, that name ras erentually issuen carlier than liimpell's ; and as we are rery rirhtly bound to acomp the carliewt arailable publiched name, Without requal as to whether its anther subsequemly rejected it or not. it frillows that Cosseyphort s should he emploved for this gemus, since Choiroutom, presumalily from previous use, is inalmissihle acerrling to its anthrir (" nom que ne ponvait pas etre conservé"). I am, howeere, unable to find any recorl of the nse of Chairodon as a generie name prior to its employment hy Blecker, aad if others who are more happily placed than I in rezard to works of reference are equally unsumesful, that name, having presedence of date. should stand. No mention of either of the Pleekerian gencra is made by Scudder ( $1-2-2$ ) or Waterhomon (19m2), hat the former catalogues a "Cossymphores. We-two.d. 1-.51," in Colenptera: it will he necessary to cancel this name if it he in use, since Blecker's emplorment of the term antedates IVest momil's hy two sears.

I append the synonymy of the genus so far as I am able to determine it:-

## THE ANNALS

AND

## MAGAZINE OF NATURAL HLSTORY.

[EIGHTH SERIES.]

No. 16. APRIL 1909.

XLLII.—Rhynchotal Notes.-XLVII. By W. L. Distant.
Heteroptera.
Fam. Lygæidæ.

## Oriental Genera and Species.

The following newly proposed genera and a number of the new species here described will be figured in the Appendix to the Rhynchota in the 'Fauna of British India.' They all pertain to the family Lygæidx as hitherto understood; but now a new departure has been advocated, and that wellknown family name is by some writers threatened with suppression. As 1 retain the name used by all previous and nearly all recent entomologists, some remarks are necessary, especially as Bergroth, in patronising the change, has written :-" As eminent hemipterists have already decided to give up the family name Lygæidæ in the hitherto recognized sense, I provisionally accept with Breddlin the name Myodochidæ after the oldest genus of the family (Myodocha, Latr.)" (Deutsch. ent. Zeitschr. 1908, p, 589). Breddin, however, is not the " eminent hemipterist" who originally advocated this idea, and Bergroth ought to have given the credit to Kirkaldy, who, however, has not been consistent with himself on the question, as he has subsequently proposed

Ann. \& Mag. N. llist. Sor. 8. Vol. iii. 22
two other new names for the same purpose. Kirkaldy's contributions to the elucidation of the question are as follows:-

Myodochide $=$ Lygreidce auct., Kirk. Entomologist, xxxii. p. 220 (1899).

Geocoridee $=$ Lygeeide auct., Kirk. Journ. Bomb. Nat. Hist. Soc. xiv. p. 306 (1902).
Pyrrhocoride $=$ Lygaidce + Pyrrhocoridce auctt., Kirk. Faun. Hawaiien. iii. pt. ii. p. 158 (1902).

We will leave these propositions by sugresting that Kirkaldy may not have yet pursued all his bibliological investigations, and that he may probably have neither said nor used the last word. Dreddin, in following Kirkaldy's first lead, has not stated why he has subsequently deserted his further suggestions, while Bergroth adds no finality by stating that he "provisionally accepts." The question solely and entirely depends on whether the name of a family should be founded on the name of the earliest genus contained in that family, and therefore less requires the attention of an eminent hemipterist so much as that of a good bibliographical clerk. And what good results from such a procedure? The evil is manifest in the addition to the labours and enigmas of the zoological recorder, and the consequent hindrance to the study of the family itself. To admit the principle in the Rhynchota would be to advocate a thorough confusion in the nomenclature of all branches of zoology. I have previously ventured to discuss the question in comexion with the name of the family Capsidæ (Faun. Brit. Ind., Rhynch. vol. ii. p. 413).

## Ethalotus indicatus, sp. n.

Above black; pronotum and corium finely, thickly, obscurely pilose; lateral margins of the pronotum (not reaching basal angles) dull sanguineous; head beneath, sternum, and legs black, prosternum dull sanguineous; abdomen beneath dull yellowish white, the apical segment black; coxæ and trochanters dull ochraceous; vertex (including eyes) twice as broad as long; ocelli about twice as far removed from each other as from eyes, between the ocelli a broad longitudinal impression, the margins of which are slightly ridged ; antennæ black, concolorous, second and third joints almost equally long, fourth longer than third; pronotum distinctly coarsely punctate, strongly transversely impressed, the anterior lobe thus well defined; scutellum with a strong central ridge,
membrane not passing the abdominal apex ; rostrum reaching the intermediate coxæ; first joint of the posterior tarsi shorter than second and third together.

> Long. $5 \frac{3}{4} \mathrm{~mm}$.
> Hab. Tenasserim; Myitta (Doherty).

Larger than AL. horni, Bredd.; first joint of posterior tarsi distinctly shorter than the second and third joints together ; antenne concolorous; eyes black; prosternum sanguineous, \&c.

## Lygঞeиs simla, sp. n.

Black; pronotum with the anterior and lateral margins (the latter not reaching basal lateral angles) and a central longitudinal fascia sanguineous; corium sanguincous, with a broad, central, obliquely transverse, black fascia, not quite reaching clavus; body beneath and legs black; lateral margins of sternum, anterior margin of prosternum, acetabulæ, and posterior segmental margins (beyond middle of abdomen widened towards lateral margins), sanguineous; antennæ robust, second joint longest, third and fourth joints about equal in length ; pronotum with the anterior and lateral margins broadly and strongly ridged, the central sanguineous line marking a distinct longitudinal carination, the disk finely punctate; scutellum with a central longitudinal carination ; clavus somewhat coarsely punctate ; corium finely punctate; rostrum passing the intermediate, almost reaching the posterior coxæ; posterior tarsi with the first joint about as long as second and third joints together.

Long. $9-10 \frac{1}{2} \mathrm{~mm}$.
Hab. Simla Hills; Matiana (Annandale).

## Lygceus eous, sp. n.

Sanguineous; antennæ, eyes, a central basal spot to head (containing a small sanguineous spot at base), two large transverse spots at base and preceded by two transverse lines to pronotum, scutellum, clavus (excluding base), a large oblong spot outside clavus posteriorly connected with a costal spot beyond middle of corium, membrane, rostrum, legs, a spot on each side of prosternum, disks of meso- and metasterna, and abdomen beneath black: lateral margins of abdomen to a little beyond middle sanguineous, apex of membrane broadly hyaline; antennæ moderately robust, second and fourth joints subequal in length, each a little longer than third; head punctate; pronotum more sparingly and coarsely punc. fate, transversely depressed behind middle at the region of
the black basal spots, the lateral and anterior margins ridged ; scutellum mutilated in type by pin; clavis coarsely, corium very fincly punctate; rostrum very slightly passing the intermediate coxæ.

Long. 6 mm .
Hab. Calcutta.

## Aspilocoryphus? modestus, sp. n.

Head black, with a small dull ochraccous spot at base; antenne dull ochraceous, the basal joint a little darker, the apical joint piceous ; pronotum piceous, the lateral and apical margins, the central longitudinal carination, and a transverse series of four large spots (two on each side of the central carination) dull ochraceous; scutellum piceous black, its apex dull ochraceous; corium dull ochraceous, an apical fascia to clavus, and longitudinal streaks between the veins of corium, black or piceous; membrane black, the apical margins broadly dull pale plumbeous, some of the veins greyish white; body beneath picenus black, shortly and closely ochracenusly pilose; margins of the sternal segments and the legs sordidly ochraceous, femora (excluding apices) brownish; rostrum and a spot on each side of the posterior margins of the pro- and mesosterna piceous ; second joint of antennæ longest, third shorter than fourth; pronotum transversely impressed before middle, distinctly, centrally, longitudinally carinate, the black or piccous anterior area with two very distinct transverse cicatrices on each side ; membrane not passing ablominal apex ; rostrum passing the intermediate coxæ.

Long. 4 mm .
Hab. Bombay (Dixon).

## Consivius, gen. nov.

Pody clongate; head subtriangular, somewhat acutely produced at apex ; ocelli placed nearer eyes than to each other ; antemm with the first and fourth joints distinctly thickened ; rostrum reaching or slightly passing the intermediate coxæ; pronotum moderately narrowed in front, granulose, a distinct transverse ridge near anterior margin; scutellum about as long as broad, the lateral margins (except at base) distinctly iidged, the apical margin strongly ridged, granulosely punctate ; membrane considerably passing abdominal apex; lateral margins of metasternum oblique and apically acutely produced, seen above on each side of the costal margins of corium; legs somewhat slender, posterior
tarsi with the first joint distinctly longer than the second and third joints together.

Allied to Arocatus by the long scutellum, but differing from that genus by the structure of the scutellum and by the produced metasternal lateral angles.

## Consivius collinus, sp. n.

Body above sanguineous; antennæ, eyes, an angular patch on each side of base of head (including the ocelli), anterior marginal area, and a transverse somewhat bimaculate spot on each side of base of pronotum, basal half of scutellum, clavus, two spots on inner margin of clavus, and a large transverse spot behind middle of corium, the apical angle of the latter, and the membrane black, apical margin of the membrane paler ; body beneath sanguineous, rostrum, basal margin of head, anterior marginal areas of pro-and mesosterna, a prominent spot on the lateral areas of both meso- and metasterna, transverse fascire to abdominal segments (not reaching lateral margins), coxæ and legs, black; excluding membrane and including legs and antennæ greyishly pilose, the head at anterior margin very longly pilose ; antennæ with the second, third, and fourth joints about subequal in length, first and fourth distinctly incrassated; pronotum somewhat coarsely granulose ; scutellum coarsely granulosely punctate.

Long. 10 mm .
Hab. Simla Hills.

## Nysius minor, sp. n.

Resembling $N$. ceylanicus, Motsch., but as a rule smaller in size ; antenne with the second and third joints ochraceous or brownish ochraceous, first and fourth joints more or less piceous, second and third joints of antennæ subequal in length, whereas in $N$. ceylanicus the second joint is distinctly longer than the third, and all the joints piccous in coloration.

Long. 3 mm .
Hab. Bengal ; Pusa and Patna.

## Nysius lacustrinus, sp.n.

Head ochraceous, the margins of the central lube black and a black cicatral punctate fascia on each side before eyes exteuding from above antennæ to base; antenuæ brownish ochraceous, the basal joint blackish; pronotum ochraceous, darkly punctate, and thus forming longitudinal fascies; scutellum piceous brown, a pale central line on apex; body
beneath and legs ochraceous; sternum with a central greyish and a lateral plumbeous longitudinal fascia, posterior margin of metasternum greyish white, head beneath greyish ; abdomen with the base and lateral margins more or less plumbeous; legs pale ochraceous, fenora spotted with castaneous, apices of tarsi black; rostrum black, slightly passing the posterior coxæ ; antennæ with the second joint longest, fourth joint a little longer than third; head with the punctures coarse; pronotum transversely impressed before anterior area, which is coarsely punctate, the other punctures also coarse; scutellum more finely punctate, the basal area a little gibbous; corium hyaline, with a yellowish tint, two black lines on its apical margin ; membrane hyaline, considerably passing the abdominal apex; sternum eoarsely punctate.

Long. 4 mm .
Hab. N.W. India ; Kumaon, Bhim Tal.
Allied to N. dohertyi, Dist., but differing by the larger size, differently coloured and longer antenne, though tue relative lengths of the joints are much the same, scutellum more gibbous, \&c.

## Nysius melanicus, sp. n.

Hearl, pronotum, and scutellum thickly piceously or blackly punctate; antennæ black, apex of fourth joint slightly brownish ochraceous; body beneath and legs black; coxæ, extreme apices of the femora, tibir, and tarsi brownish ochraceous; corium pale obscure luteous hyaline, the costal area clear and unspotted, the veins, and the apical margin medially interrupted, piceous or black; second joint of antemne distinctly longer than the third, third and fourth joints almost subequal in length ; pronotum coarsely punctate, with a somewhat obscure central longitudinal ridge; scutellum with a longitudinal ridge commencing at about one-third from base, where it is distinctly tuberculous; membrane hyaline, considerably passing the abdominal apex; rostrum reaching the intermediate coxæ.
Long. 4 mm .
Hab. Kumaon, Bhim Tal ; Simla Hills, Theog.

## Pirkimerus nicobarensis, sp. n.

Head, pronotum, scutellum, and body beneath piceous brown ; first, second, and third joints of antennx, rostrum, and legs ochraceous; fourth joint of antennæ piceous brown ; hemelytra pale umber-brown ; outer margin of clavus, an
elongate marginal spot before middle, and a marginal spot to membrane pale ochraceous; between these spots the margin is much darker ochraceous; second and third joints of antennæ subequal in length, each a little longer than first, fourth longest, incrassate and pilose; pronotum strongly transversely impressed, punctate and wrinkled at anterior margin, the posterior area discally foveately depressed, anteriorly coarsely punctate, posteriorly finely transversely striate; scutellum distinctly centrally longitudinally carinate; membrane not quite reaching the apical abdominal segment; posterior femora finely spined beneath, the posterior tibio strongly marginally setose ; basal joint of posterior tarsi much longer than the second and third joints.

Long. 5 mm .
Hab. Nicobar Islands; IIomfray's Sts. (Rogers, Brit. Mus.).

## Macropes raja, sp. n.

Head, antennæ, pronotum, scutellum, abdomen above, body beneath, and femora black; first and second joints of artennæ (excluding extreme apices of second joint), tibir, and tarsi pale ochraceous; hemelytra milky white; internal vein and margins of clavus, two principal veins of corium on apical half, the oblique margin separating corium from membrane, two internal curved veins and a large discal spot to membrane, piceous; second and fourth joints of antennæ subequal in length, each a little longer than third; pronotum with the anterior area or lobe smooth and centrally longitudinally grooved or sulcate, the posterior area or lobe coarsely punctate and depressed, with a distinct transverse ridge before basal margin, the lateral margins concave; hemelytra reaching the anterior margin of the fifth abdominal segment ; rostrum passing the anterior coxæ.

Long. 6 mm .
$H a b$. Calcutta.
This species is allied to both M. spinamanus, Motsch., and M. punctatus, Walk., by the sulcated anterior pronotal lobe: from $M$. spinamanus it is to be separated by the longer hemelytra and the colour of the legs; from M. punctatus it differs in the smaller size, the ochraceous first and second antennal joints, more distinct sulcation to pronotum, ochraceous tibiæ, \&c.

## Macropes singularis, sp. n.

Head, pronotum, scutellum, body beneath, and legs black;
apices of femora and the whole of the tibire more or less castaneous; tarsi ochraceous; antenme piceous brown, the extreme apices of the joints paler ; ocelli shining carminered; hemelytra creamy white, costal margin of corium slightly yellowish, clavus, corium at claval margin and apical area to corium black; basal area of membrane (not reaching inner margin) and narrowly connected with a large clongate spot (which almost extends to lateral and apical margins) black; abdomen above black; second and third joints of antennæ subequal in length, fourth longer than either second or third; pronotum elongate, centrally as lone as broad at base, punctate, transversely impressed behind middle and thence roundly narrowed to head, basal margin concave, a smail pale impunctate spot near each basal lateral angle; scutellum punctate excepting basal area, a central longitudinal ridge extending from about middle to apex ; hemelytra reaching base of apical abdominal segment; rostrum slightly passing anterior coxæ, black, with the apices of the joints a little paler.

Long. $6 \frac{1}{2} \mathrm{~mm}$.
Hab. Ceylon; Pundaluoya (Green).

## Macropes uniformis, sp. n.

Ifead, pronotum, scutellum, and stemum black; antemre with the first, second, and third joints dull ochraceous, fourth joint black, its base ochraceous; apex of head, posterior margin of pronotum, and legs castancous; rostrum, tibier, and tarsi more or less ochraceous; corium very pale stramineous; membrane very pale greyish brown; abdomen piceous brown, thickly, finely, greyishly pilose; antenna with the third joint longer than second, fourth considerably longer than either second or third; pronotum with the anterior lobe subglobose, broad, shining, obscurely centrally longitudinally sulcate on disk, sparingly punctate, the transverse constriction about onc-third from base, the basal area transversely wrinkled or striate, the anterior lobe laterally a little convexly ampliated, the posterior margin concave; scutellum short, broad, centrally longitudinally ridged from about middle to apex; membrane extending to the penultimate segment of the abdomen ; anterior femora strongly incrassated and shortly spined beneath.

Long. 5 mm .
Hab. Calcutta.
Allied to M. subauratus, Dist., by the uniformly coloured
corium and membrane; from that species it differs in the colour of the antenne and legs, the broader and more globose anterior pronotal lobe, the shorter membrane, $\& c$.

## Macropes privus, sp. n .

Head, antennæ, eyes, pronotum, and scutellum black, moderately shining; body beneath and legs black, apices of the femora and the whole of the tibire pale castaneous, tarsi ochraceous; clavus and corium greyish white, the claval suture and the outer marginal area to corium (widened posteriorly) piceous; membrane black, its basal angle greyish white ; antenne with the extreme apices of the joints paler, second and third subequal in length, fourth longest, pyriform and palely pilose ; pronotum considerably longer than broad, thickly punctate, the basal margin concave, two smooth cicatrices in transverse series on anterior area, and two similar but narrower cicatrices near middle; scutellum distinctly ridged, transversely at base, and centrally longitudinally, its disk finely granulose; margins of clavus, the subclaval vein to corium, and the imner half of the apical margin to corium pale yellowish ; membrane smooth, shining, reaching the base of the sixth abdominal segment; connexivum and abdomen beneath very shortly but thickly ochraceonsly pilose, the latter with a double series of small black points on each side; rostrum shining piceous black, about reaching the anterior cosæ; anterior femora strongly incrassate, finely spined beneath.

Long. $5 \frac{1}{2} \mathrm{~mm}$.
Hab. Ceylon; Peradeniya (Green).
Allie! to M. precerptus, Dist., but smaller, anterior lobe of pronotum not suleate, colour of membrane, corium, and legs different, \&c.

## Macropes thoracicus, sp. n.

Head, pronotum, scutellum, and sternum black; basal margin of pronotum and the abdomen pale testaccous ; rostrum and legs orange-yellow ; corium very pale ochraceous; membrane creamy white ; antennæ piceous or black, the basal joint and extreme apices of second and third joints ochraceous, second and fourth joints subequal in length, each considerably longer than third; pronotum short, a little broader than long, transverse impression about onefourth before posterior margin, the anterior area or lobe opaque, coarsely irregularly punctate; corium shorter than
membrane, which extends to the penultimate segment of the abdomen; rostrum reaching the anterior coxæ; anterior femora moderately incrassated, obscurely spinous beneath.

Long. 5 mm .
Hab. Nepal.
By the uniformly coloured corium and membrane allied to M. subauratus and 11. uniformis. From both it differs and is subgenerically distinct by the shorter and comparatively broader pronotum and the short posterior area or lobe, tho short corium, \&c.

## Ischnodemus erebus, sp. n.

Head, pronotum, scutellum, abdomen above, and body beneath black; corium dull ochraceous, streaked longitudinally with castaneous brown; membrane (reflecting the dark abdomen beneath) black; femora black, their apices and the whole of the tibiæ and tarsi brownish ochraceous; antennæ brownish ochraceous, apical joint (excluding base) blackish, second joint slightly longer than the third, fourth joint considerably longest ; vertex thickly finely granulose; pronotum coarsely punctate and granulose, finely pale pilose, more longly pilose on lateral margins, some obscure tuberculous elevations on anterior disk; scutellum granulose and punctate, palely pilose, a little depressed on disk; corium somewhat strongly palely pilose, especially on lateral margins; membrane neither reaching the abdominal apex nor covering the comexivum, which is exposed for nearly its entire length.

Long. $2 \frac{1}{2}-3 \mathrm{~mm}$.
Hab. Bombay Province; Matheran, 2500 feet (Pusa Coll.).

Differing from I. noctulus, Dist., by its smaller size, the exposed connexivum, absence of subapical pale spot to membrane, the granulose head, pronotum, and scutellum, pale anterior tibiæ, \&c. I have examined a series of this species, but, unfortunately, all the specimens were in a somewhat greasy condition, which rendered the colourcharacters more or less difficult to identify, especially as regards the hemelytra.

## Ischnodemus atromaculatus, sp. n .

Head, pronotum, and scutellum black, palely pilose; corium pale ochraceous, with the basal angle and a large spot near apex black; membrane blackish, its basal angle and a spot near the apical margins of corium pale ochraceous;
body beneath black; femora black, their apices and the whole of the tibiæ and tarsi pale ochraceous; antennæ black, second joint a little longer than third, fourth longest and thickest ; vertex finely granulose, subacutely prominent anteriorly; pronotum somewhat coarsely granulose, about as long as broad at base, the lateral margins a little convexly rounded ; scutellum sparingly but coarsely granulose; membrane not quite reaching abdominal apex nor covering connexivum; corium strongly palely pilose, covering or almost covering the connexivum.

Long. 2-2 $\frac{1}{2} \mathrm{~mm}$.
Hab. Bombay Province; Matheran, 2500 feet, Igatpuri, 2000 feet (Pusa Coll.).

As in the previous species, the specimens on which this is founded are in a more or less greasy condition, which renders the coloration difficult to determine. This more particularly applies to the membrane, which in some examples appears to be brownish grey, with the veins piceous.

Besides the distinct markings of the corium the species is to be recognized by the broader and comparatively shorter pronotum, with its more convexly rounded lateral margins.

## Nerthus, gen. nov.

Elongate; head broad, convexly narrowed in front of eyes, central lobe prominent and slightly produced; antennæ with the first joint shortest, distinctly shorter than the head, second joint a little longer than either third or fourth; rostrum just passing the posterior cozæ, first joint passing base of head, second and third subequal in length; ocelli near posterior margin, nearer to eyes than to each other; pronotum elongate, moderately laterally sinuate, transverse constriction distinct, anterior lobe convex, a little shorter than posterior lobe, which is deflected anteriorly, the posterior lateral angles rounded, their posterior margins slightly lobately produced; scutellum a little longer than broad, with a discal longitudinal carination; corium a little more than half the length of abdomen and concavely constricted at middle; membrane reaching apex of abdomen; legs moderately long, unarmed, pilose, femora moderately evenly thickened; posterior tibire with the basal joint a little longer than the remaining joints together; abdomen beneath with a distinct, central, longitudinal, carinate line.

Allied to Artemidorus, Dist., but differing by the basal joint of antennæ being shorter than the head; the much longer iostrum and the relative lengths of joints of same, the
shorter and evenly thickened posterior femora, not attenuated towards base and incrassate at apices as in Artemidorus.

## Nerthus dudgeoni, sp. n.

Head, antennæ, pronotum, scutellum, abdomen above, rostrum, and body beneath black; posterior margin of pronotum, central apical longitudinal carination to scutellum, and clongate (almost connected) spots to connexivum very pale ochraceous; base of first joint of antennæ and the legs reddish yellow ; apical angle of corium and the tarsi black; bases of intermediate and posterior femora stramineous; head, pronotum, and sternum thickly coarsely punctate; clavus longitudinally punctate; corium with the subclaval margin and the costal margin longitudinally punctate; body bencath (especially the abdomen) finely greyishly pilose; other structural characters as in generic diaguosis.

Long. 9 mm .
Ilab. Kangra Valley, 4500 feet (Dudgeon).

## Chauliops nigrescens, sp. n.

Head pale castaneous brown, with an obscure darker longitudinal fascia on each side between the bases of antennæ and the ocelli ; antemne pale ochraccous, the first and fourth joints brownish ochraceous; pronotum sordidly ochraceous, thickly piceously punctate, a black subanterior marginal fascia (interrupted at middle) and a pale central longitudinal line; scutellum piceous black; corium sordidly ochraceous, the clavus and apical area of corium piceous black; membrane sordidly greyish, with piceous suffusions; connexivum pale luteous, spotted with black; body beneath and legs dull black ; coxæ, bases of femora, a broad central annulation to tibiæ, and the tarsi pale ochraceous; antennæ robust, second and third joints slender, second longest, fourth slightly longer than third ; pronotum gibbously rounded, much as in C. lobatula, Bredd.; corium distinctly shorter than membrane, which very slightly extends beyond abdominal apex; abdomen beneath coarsely granulose.

Long. 3 mm .
IIub. N.W. India; Kumaon, Bhim Tal (Lnd. Mus. and Coll. Dist.).

## Epibomius, gen. nov.

Subelongate; head about as long as breadth between eyes, somewhat abruptly pointed in front, the lateral margius
between lase of antennæ and apex convexly sinuate, ocelli a little in front of basal margin and on each side near eyes; antemm moderately robust, pilose, the third and fourth joints prominently pilose; rostrum reaching the intermediate coxæ; pronotum about as long as broad at anterior margin, transversely impressed near middle, the anterior margin very slightly sinuate, lateral margins almost straightly oblique, posterior margin truncate, centrally faintly longitudinally carinate ; corium considerably longer than membrane, which scarcely passes the abdominal apex, and with the basal cells distinct; femora moderately thickened.

Near Sadoletus, Dist.

## Epibomius pusa, sp. n.

Head black ; antennæ picrous, greyishly pilose ; pronotum pale castaneous red, the anterior and posterior areas more or less black; corium black, very finely greyishly pilose, the basal and apical angles testaceous; head beneath black; sternum pale castaneous red, with its disk black; abdomen beneath and legs sordicly ochraceous, the former with its base and apex black; comexival border beneath pale lutcous, with black spots; head thickly obscurely punctate ; antemı with the second joint longest, third and fourth strongly pilose, fourth joint slightly longer than third; pronotum sparingly very coarsely punctate, its lateral margins prominently pilose ; corium obscurely punctate and more distinctly pilose ; sternum sparingly coarsely punctate.

Long. $3 \frac{1}{2}-4 \mathrm{~mm}$.
Hab. Bengal ; Pusa (Lefroy).

## Sadoletus pallescens, sp. n.

Head, pronotum, and scutellum dark brownish ochraceous; eyes and two large oblique spots on posterior lobe of pronotum black; corium pale ochraceous; membrane pale hyaline; antennæ, rostrum, body beneath, and legs pale ochraceous; meso- and metasterna dark brownish ochraceous, posterior lateral angles of the latter pale ochraceous; antemme with the extreme apices of the second and third joints and the apical joint (excluding base) more or less piceous; tibir biannulated with pale brownish, apices of tarsi piceous, posterior femora with a fuscous spot on upper surface a little beyond middle ; antennæ with the second joint slightly longer than the third, fourth joint slightly or scarcely louger than the scond; posterior lobe of pronotum somewhat coarsely
punctate ; scutellum finely obscurely punctate on basal, much more strongly punctate on apical area ; clavus longitudinally punctate, corium linearly and more sparingly punctate.

Long. 5 mm .
$H a b$. Calcutta.
Differs from S. validus, Dist., by the differently coloured head and pronotum and the much less or scarcely pilose character of the same.

## Esmun, gen. nov.

Body oblong; head about as long as breadth between eyes, central lobe prominent and moderately projecting; ocelli near base a little nearer to eyes than to each other; rostrum reaching or just passing the anterior coxæ, first joint not reaching base of head; antennæ moderately robust, first joint scarcely reaching apex of head, fourth joint incrassated; pronotum broader than long, before middle roundly narrowed to eyes, obsoletely transversely depressed near middle, posterior margin moderately concave, anterior margin nearly straight; scutellum broad and short; hemelytra shorter and narrower than the abdomen, corium shorter than membrane at its greater central length, its apical margin sinuate, membrane with distinct basal cells and scarcely passing the base of the last abdominal segment; femora moderately iucrassate, posterior tarsi with the basal joint shorter than the second and third joints together.

Near Dinomachus, Dist.

## Esmun typicus, sp. n.

Head, antennæ, rostrum, scutellum, abdomen above, and body beneath and legs black; base of fourth joint of antemnæ rusty brown ; eyes and apices of the tibir castaneous brown; tarsi pale ochraceous; corium pale stramineous, base of clavus, two very small spots at claval apex, and the apical margins of corium (broadly and irregularly) black; membrane hyaline, centrally slightly tinged with fuscous brown; antennæ with the third joint shorter than second or fourth, fourth longer than second; head granulose and punctate; pronotum coarsely punctate, two subcallosities on anterior area less punctate, the central area somewhat broadly trans* versely depressed; scutellum opaque; abdomen above very finely greyishly pilose.

Long. $3 \frac{1}{2} \mathrm{~mm}$.
Hab. Bombay (Dixon).

Euhemerus, gen. nov.
Broad, subovate; head nearly as long as breadth between cyes; antennæ moderately robust, first joint not reaching apex of head; ocelli situate near eyes; rostrum almost reaching the intermediate coxæ, first joint almost reaching base of head; pronotum much broader than long, the anterior angles rounded, posterior margin a little concave, anterios margin slightly concave for the reception of head, near middle centrally transversely impressed; scutellum very short and broad; hemelytra a little shorter and considerably narrower than the abdomen; corium shorter than central length of membrane, its apical margin irregularly concave; membrane with distinct basal cells and not quite reaching the abdominal apex; femora moderately thickened, posterior tarsi not quite as long as the second and third joints together.
Allied to Esmun, Dist.

## Euhemerus latus, sp. n.

Head, pronotum, scutellum, abdomen above, and body beneath black; antennæ, lateral margins of connexivum, rostrum, and legs castaneous brown, apices of the femora, intermediate and posterior tibiæ, and the tarsi ochraceous; corium greyish white, margins of clavus, two spots at claval apex, and the longitudinal veins to corium brownish, apical angular areas black; membrane hyaline; antennæ with the second joint longer than the third but shorter than the fourth joint; head and pronotum thickly rather coarsely punctate; scutellum opaque; connexivum and ablomen beneath thickly, shortly, greyishly pilose.

Long. $3 \frac{1}{2} \mathrm{~mm}$.
Hab. Bombay (Dixon).

## Pamerana, gen. nov.

Head shorter than pronotum, but longer than the anterior lobe, ocelli near base and nearer to eyes than to each other, antenniferous tubercles prominent and outwardly produced in a short spinous tubercle, the apex of the central lobe distinctly produced ; antennæ with the first joint shorter than head, second joint slightly longest, third and fourth subequal in length ; rostrum reaching the intermediate coxæ, first joint not reaching base of head; pronotum with a narrow anterior collar, the anterior lobe subglobose and about as long as
posterior lobe ; scutellum about as long as broad ; claviss and costal area of pronotum coarsely thickly punctate, the corium inwardly more finely punctate; mombrane slightly passing the abdominal apex; anterior femora thickened, distinctly spined beneath, anterior tibie a little dilated at apex, all the tibier about as long as the femora, posterior tarsi with the basal joint much longer than the remaining joints together.

The spinously produced antenniferous tubercles are a prominent character in this genus, which is allied to Pamera.

## Pamerana cuneata, sp.n.

Head, pronotum, scutellum, clavus, and corium dull black, head more shining black; anterior pronotal collar (interrupted at middle), two central longitudinal spots on posterior pronotal lobe, margins of clavus, subclaval veins, and a spot near inner posterior angle of corium pale castaneous brown; membrane fuscous brown, with the veins dull ochraceous; antennæ black, apical joint with a broad pale ochraceous amulation; body beneath black, rostrum and legs pale ochraceous; femora, tibix, and tarsi slightly piceous towards apices; pronotum thickly finely punctate; scutellum sparingly punctate, more distinctly so on lateral margins ; other structural characters as in generic diagnosis.

Long. 7 mm .
Hab. Calcutta.

## Eucosmetus mimicus, sp. n.

ㅇ. Head, pronotum, scutellum, and body beneath shining black; antenne stramineous, the apical joint (excluding base) piccous ; rostrum stramineous, the basal joint black; legs stramineous, anterior femora (excluding apices) black, intermediate femora (excluding base) castaneous, posterior femora (excluding base) piceous; corium greyish white, a longitudinal streak to clavus, a streak near basal costal margin, and a broad central transverse fascia crossing apex of clavus cinnamon-brown; in this fascia beyond claval apex is a small white spot in each corium, a black transverse spot near apical angle ; membrane black, narrowly white at basal outer angles, and with a white spot at apex ; antenne with the first joint reaching apex of head, second and third longest and subequal in length ; posterior lobe of pronotum coarsely punctate; clavus longitudinally punctate, the transverse fascia to corium somewhat coarsely punctate; membrane very slightly passing abdominal apex; anterior tibice (f) not spined.

Long. 5 mm .
Hab. Pegu (Coll. Dist.).
This species, apart from the generic character of the eyes, possesses a simulative appearance to Caridops gibba, Bergr.

## Maramaldus, gen. nov.

Head long, broad and convex, constricted behind the eyes, the central lobe distinctly prominent at apex ; antenur with the first joint distinctly passing apex of head, second and third joints subequal in length, each longer than fourth; rostrum slightly passing the anterior coxæ, first joint not nearly reaching base of head; pronotum with the anterior lobe (including collar) more than twice as long as posterior lobe, with a distinct broad anterior collar, convex, narrowed anteriorly and posteriorly, smooth and shining, the collar coarsely punctate, posterior lube coarsely punctat: (except near its anterior margin), its lateral angles distinctly acutely spined ; scutellum slightly longer than broad, coarsely punctate; abdomen moderately concavely constricted on basal half, its apex truncate ; anterior femora strongly incrassate, strongly constricted at base and moderately marrowed at apex, spined bencath; tibiæ curved, not spined in of ( $\delta$ unknown) ; hemelytra not reaching apex of abdomen.

Allied to Eucosmetus, but first joint of antennæ distinctly passing apex of head, anterior lobe of pronotum longer and with a broad anterior collar, hemelytra not reaching apex of abdomen, \&c.

## Maramaldus admistus, sp. n.

Head, pronotum, scutellum, and body beneath shining black; anterior collar and posterior lobe more opaque and strongly punctate ; antennæ stramineous, finely pilose, apical joint (excluding base) piceous; rostrum ochraceous, the basal joint picenus; legs stramineous, anterior femora (excluding apices) shining black, anterior and intermediate femora with their apical areas piceous; connexivum spotted with stramineous; corium castaneous brown, spotted with white, the principal spots being an elongate one on both costal and claval margins, the largest near apical angle, and a small rounded spot near claval apex, clavus and anterior half of costal margin with longitudinal series of punctures, a transverse series of punctures before membranal division, which is distinctiy paler; membrane piceous, with a white spot at apex; other structural characters as in generic diagnosis.

Long., $\circ$, 6 mm .
Hab. N.W. India; Kumaon.
Ann. \& Mag. N. Hist. Ser. 8. Vol. iii.

## Agunga fulgida, sp. n.

Head and anterior lobe of pronotum shining black, posterior pronotal lobe brownish ochraceous, thickly darkly punctate, the lateral margins (narrower on anterior lobe) stramineous, the posterior lateral angular margins black; scutellum black; coriun pale nchraceous, with two short, black, costal, marginal lines (one near middle, the other on apical area), clavus and posterior disk blackly punctate, an obscure greyish-white spot at each interior angle; membrane yellowish white, with the veins darker; body beneath black, lateral margins of sternum ochraccous, but anteriorly and posteriorly castancous; legs ochraceous, anterior femora (excluding apices) and a subapical annulation to intermediate and posterior femora black or piceous; antemæ with the first and second joints stramineous, base of second joint black, third black, fourth ochraceous, with its base black, second, third, and fourth subequal in length; head and anterior lobe of pronotum thickly finely punctate, the latter strongly convexly raised and anteriorly deflexed, posterior pronotal lobe more sparingly and coarsely punctate ; scutellum coarsely punctate.

Long. $2 \frac{1}{2} \mathrm{~mm}$.
Hab. Calcutta.
Differing principally from A. crassa, Dist., by the shining head and pronotum, which is opaque in crassa; anterior pronotal lobe more gibbous and only slightly longer than posterior lobe, in crassa the pronotum is wholly black, in fulgida the anterior lobe is only black, head more vertically depressed, \&c.

## Diniella bengalensis, sp. n.

Head, pronotum, and scutellum shining hack ; pronotum with the basal margin (very namowly) and the posterior: lateral angles ochraceons ; antemæ and corium ochraceous, the latter with a transverse castaneous fascia crossing from costa to inner angle, and then broadly continued on inner half of apical margin; membrane pale hyaline; body beneath black; legs and rostrum ochraceous; antemnæ robust, first joint shorter than sccond, second and third subequal in length, each a little shorter than fourth; head sparsely finely punctate ; pronotum more coarsely punctate, with indications of an obscure transverse impression ; clavus finely sparingly longitudinally punctate, corium at claval suture with two longitudinal rows of conrse punctures, disk of corium more
sparingly and irregularly punctate; first joint of rostrum thickened and passing base of head.

Long. 3 mm .
Hab. Bengal.
Allied to D. nitida, Reut., from Madagascar and the Seychelles.

## Teutates, gen. nov.

Head about as long as breadth between the outer expanse of eyes, broadly obtusely produced before insertion of antennæ, the margins of the central lobe prominent, eyes not quite reaching the anterior angles of the pronotum ; antemnæ with the first joint not reaching apex of head, second joint about one and a half times the length of the first (remaining joints mutilated in type) ; rostrum reaching the apex of the anterior coxæ, first joint not extending to base of head, secoud and third joints subequal in length; pronotum a little more than half the length at base, the lateral margins rounded anteriorly and narrowly dilated, anterior area with two small central tubercles, four longitudinal carinate line; of which the central two are less developed and do not reach the base, posterior margin truncate, the anterior margin very slightly sinuate; scutellum a little shorter than broad at base, the lateral margins slightly sinuate, the disk foveate and punctate; margins of the corium slightly rounded; membrane not passing the apex of the abdomen, the veins simple; legs of moderate length ; anterior femora not spined beneath.

I place this genus near Arrianus, Dist.

## Teutates sculpturatus, sp. n.

Above dull ochraceous, eyes and margins of the central lobe to head piceous ; pronotal tubercles brownish ochraceous; body beneath paler than above, the anterior acetabule darkly margined, a broad castaneous longitudinal fascia on each lateral abdominal area; pronotum thickly and more darkly punctate, the lateral margins paler and almost impunctate; scutellum darkly coarsely punctate, the margins of the foveate area raised and almost impunctate; corium semihyaline, coarsely punctate, the clavus longitudimally punctate ; sternum punctate, other characters as in generic diagnozis.

Long. 3 mm .
Hab. Calentta.

## Aphanus dudgeoni, sp. n.

Head pale dull castaneous, with irregular black lines; antennæ ochraceous, basal joint much motiled with black, apices of second and third joints and fourth joint (excluding base) piceous; pronotum ochraceous, thickly brownly punctate, the disk of the anterior area and the lateral margins much more sparsely punctate; scutellum ochraceons, thickly brownly punctate, the extreme apex pale ochraceons; tegmina brownish, tlickly punctate, the lateral margin ochraceous, sparsely blackly punctate, the apical angle and a spot Lefore it blackish, some obscure basal suffinsions and two small spots about middle of apical area, pale nchrac ous; membrane brownish ocluaceous, with darker mottlings, the basal area black traversed by the paler veins, a smail pale ochraceous spot behind apical angle of corium; head beneath, rostrum, sternum, and legs ochraceous, apices of tibiæ piceous, excluding head darkly punctate, central area of meso- and metasterna black; abdomen beneath somewhat testaceous; basal joint of antennæ moderately thickened, with prominent spinous hairs, fourth joint a little longer than third or second; rostrum slightly parsing anterior coxe; pronotum strongly transversely impressed near middle, the lateral margins laminate, anterior femora shortly spinous beneath, but with a longer spine before apex ; intemediate and posterior tibix prominently spinslose.

Long. $7 \frac{1}{2} \mathrm{~mm}$.
Hab. Kangra Valley, 4500 feet (June, G. C. Dudgeon); Purneah District (Paiva, Ind. Mus.).

This species was taken by the same collector at the same locality and at the same time of the year as the species described by Kirkaldy as $A$. kangricus. It cannot, however, be reconciled with Kirkaldy's description, from which it seems abundantly distinct.

Aphanus ornatulus, sp. n.
Reddish ochraceous; pronotum and scutellum thickly darkly punctate, lateral margins of the pronotum pale ochraceous, with scattered black punctures; head piceous brown, with a small central ochraceous spot at base; antennæ hrownish ochraceous, the basal joint, apices of second and third joints, and the fourth joint (excluding base) piceous; corrium with the lateral margins narrowly pale ochraceous and containing a costal series of dark punctures, on apical area three large black spots, one un laterai margin before apex

Which is narrowly united to a similar spot near apex of clavus and inner angle of membrane, the third spot occupying apical angle of corium ; membrane black; sternum and legs blackly punctate, apices of femora and tibiæ narrowly blackish; antennæ with the first joint thickest and shorter than head, second a little longer than the third and slightly longer than the fourth joint; pronotum transversely impressed near middle, before which it is moderately convexly raised, clavus and corium thickly somewhat finely punctate; membrane reaching apex of abdomen; rostrum about or almost reaching the intermediate coxæ, the area of the sternum between the coxæ black; tarsi very pale ochraceous, with their apices black.

Long. 8 mm .
Hab. Nepal Terai.

## Aphanus bengalensis, sp. n.

Head reddish ochraceous; antennæ brownish ochraceous, basal joint, apices of second and third joints, and fourth joint. (excluding base) piceous; pronotum ochraceous, thickly blackly punctate, the lateral margins paler and longitudinally coarsely blackly punctate; scutellum ochraccous, darkly punctate (somewhat mutilated in type) ; clavus and corium pale ochraceous, thickly blackly punctate, the lateral margins pale and sparingly coarsely blackly punctate; a somewhat large greyish-white spot on apical margin at each side of basal angle of membrane, the apical angle of corium piceous; membraue pale brownish, the upper margins paler, and with a small but very pale spot near apical angle of corium ; prosternum ochraceous, blackly punctate ; meso- and metasterna piceous, the latter with two marginal lines and the posterior margin ochraceous and blackly punctate; abdomen beneath piceous; legs orange-yellow, sparingly, finely, blackly punctate, apices of the tibir black; first joint of antennre thickest and shorter than head, second and fourth subequal in length, each a little longer than third joint; pronotum transvorsely impressed near middle, before which it is slightly convex ; rostrum slightly passing the anterior coxæ; anterior femora shortly spined beneath; membrane very slightly passing the abdominal apex.

Long. $6 \frac{1}{2} \mathrm{~mm}$.
Hab. Bengal, Pusa (Lefroy).
Allied to A. sparsus, Dist.

## Aphanus suratensis, sp. n.

Head, pronotum, and scutellum black; lateral pronotal margins (not quite reaching base) ochraceous, two central spots on basal area of pronotum reddish ochraceous; extreme apex of scutellum ochraceous; tegmina black, corium with the outer claval margin (more or less), the costal margin for about two-thirds from base with an inner elongate spot near its base, and a large round spot near the apical margin ochraceous; membrane pale fuliginous, subhyaline ; body beneath black, lateral margins of sternum ochraceous, lateral margin of abdomen pale brownish; rostrum ochraceous, the liasal joint black; legs ochraceons, anterior femora (excluding base), apical halves of intermediate and posterior femora, and extreme apices of tibiæ l,lack; second joint of antemnæ longer than third (fourth mutilated in type) ; pronotum transversely constricted near middle, behind the constriction thickly punctate, the lateral margins laminate and impunctate ; scutellum obscurely finely punctate ; clavus thickly coarsely functate; corium (excluding costal margin) thickly punctate; anterior femora spined beneath; intermediate and posterior tibise spinulose.

Long. 8 mm .
Hab. Bombay Prov.; Surat.

## UzzA, gen. nov.

Head (including eyes) slightly wider than anterior margin of pronotum, ocelli close to basal margin, almost equally removed from eyes as from each other; antemnæ long, basal joint longer than first joint of rostrum ; first, second, and third joints almost subequal in length, each a little longer than fourth ; rostrum about reaching the anterior coxæ, first joint about or almost reaching base of head; pronotum as long as broad at base, transversely constricted a little behind middle, before which it is subglobose, the lateral margins moderately dilately anipliate, the basal margin concavely sinuate ; scutellum longer than broad ; lateral margins of corium concavely sinuate; membrane reaching or slightly passing the abdominal apex; legs long, anterior femora thickened, obtusely spined beneath, and armed with a strong spine before apex, posterior legs very long, posterior tibiæ nuch longer than the femora and about as long as head, pronotum, and scutellum together, posterior tarsi with the first joint about twice as long as the other two joints together.

Allied to Dieuches, from which it differs by laving the
basal joint of the antenuæ longer than the first joint of the rostrum; by the length of the posterior legs allied to Pcantius.

## Uzza karenia, sp. n.

Head black; antennæ piceous, base of fourth joint pale luteous ; pronotum with the anterior lobe black, the posterior lobe piceous, with a central longitudinal ochraceous line, the lateral margins (not reaching base) pale ochraccous; scutellum black, the extreme apex ochraceous; corium dark castaneous, the basal third, two marginal spots beyond middle, and the apical angles pale ochraceurz, a small spot on each side of claval aper pale testaceous; meml, rane black, with a sulbcentral, waved, transverse, greyish fascia; boly beneath black; rostrum and legs piceous, lases of intermediate and posterior tibire pale ochraceous; structural characters as in generic diagnosis.

Long. 6 mm .
Hab. Burma; Karennee.

## Naudarensia manipurensis, sp. n.

Head, pronotum, and scutellum piceous; pronotum with the middle of the lateral margins distinctly paler, antennæ with the first and second joints brownish ochraceous, apex of second joint, third (excluding base) and fourth joint piceous ; corium brownish ochraceou*, thickly darkly punctate, a small black spot near middle of costal margin, and a transverse linear pale spot before apex ; membrane fuliginous, the basal margin pale; body beneath, rostrum, and legs black or piceous; bases of intermediate and posterior femora pale ochraceous, tibiæ (excluding apices) brownish ochraceous; first joint of antennæ scarcely reaching apex of head and finely spinulose, second joint a little longer than third; pronotum about as long as broad at base, transversely compressed near middle, before which it is finely and behind which more coarsely punctate; scutellum somewhat finely punctate; clavus longitudinally punctate, corium somewhat coarsely punctate except on costal margin, membrane reaching apex of abdomen ; rostrum almost reaching the intermediate coxæ; anterior femora incrassate and shortly spinous bentath; posterior tarsi with the basal joint about twice as long as the other two joints together.

Long. 6 mm .
$H a b$. Manipur.

The membrane reaching the abdominal apex in this spereies will require a corresponding modification in the generic diagnosis.

## Neoletheus, gen. nov.

Head about as long as broad (including eyes), central lobe a little prominent at apex, ocelli near base, much closer to cyes than to cach other ; antennæ with the first joint moderately thickened, not quite as long as head, second and third joints slender, second longer than third; rostrum reaching the intermediate coxæ, first joint reaching base of head; pronotum subquadrate, slightly transversely impressed before middle, much more coarsely punctate behind the impression than before it, and containing a central longitudinal carinate line, the antenior margin truncate, more sparsely punctate, and extending on each side a little beyond eyes, the lateral margins almost obliquely straight, the anterior angles rounded, basal margin truncate, the basal lateral angles longitudinally ridged; scutellum triangular, about as long as broad, discally depressed; membrane slightly passing abdominal apex, venation generally as in Lethceus; femora incrassate, the intermediate less and the posterior femora a little more so, the anterior femora shortly spined beneath, the intermediate and posterior femora somewhat spinously hirsute, tibiæ spinulose, posterior tarsi with the basal joint twice as long as the remaining joints together.

## Neolethceus typicus, sp. n.

Black; two small spots to c'avus, two on corium (one near middle, the other near apical margin), second and third joints of antennæ, rostrum (excluding basal joint), tibio, and tarsi more or less ochraceous; basal joints of antenne and rostrum, femora, and apices of tibiæ and tarsal joints castaneous brown; head (excluding central lobe) punctate; pronotum before the faint transverse impression finely, behind it coarsely punctate ; scutellum foveately impressed and somewhat sparingly punctate, the lateral marginal areas more thickly and coarsely punctate; corium thickly and finely punctate, the veins prominent, clavus with two longitudinal series of punctures; membrane brownish ochraceous.

Long. $9 \frac{1}{2} \mathrm{~mm}$.
Hab. Burma ; Palon.

## Usilanus, gen. nov.

Head somewhat long, subtriangnlar, about or almost as long as the anterior lobe of the pronotum, the central lobe distinctly produced and projecting in front, ocelli near base, much nearer to eyes than to each other; antenne with the first joint moderately thickened, shorter than head but passing its apex, second, third, and fourth joints almost subequal in length; rostrum reaching the intermediate coxæ, first joint slightly passing the base of head, second not reaching the base of prosternum ; pronotum shorter than breadth at base, the lateral margins obliquely rounded, transversely impressed behind middle, the anterior margin scarcely or only slightly broader than the eyes, the anterior lobe subglobose, the basal area or posterior lobe coarsely punctate, faintly, centrally, longitudinally ridged, and here the lateral margins are a little laminate, posterior margin distinctly concave before scutellum, the anterior margin truncate; scut:llum triangular, slightly longer than broad at base; clarus longitulinally punctate, corium with the subcostal vein distinctly curved; membrane slightly passing the abdominal apex, with four longitudinal veins, the two inner strongly curved towards base and reaching basal margin, the two outer not reaching basal margin; anterior femora incrassate and somewhat continuously but irregularly spined beneath, anterior tibix a little curved, somewhat flattened and also shortly spined beneath on their apical halves, intermediate and posterior legs moderately slender, the tibice sutose, first joint of the posterior tarsi about one and a half times as long as the remaining joints together.

Allied to the genus Eremocoris.

## Usilanus burmanicus, sp. n.

Body above black, lateral margins of the corium narrowly ochraceous ; antennæ piceous, about its basal half pale ochraccous; head beneath and stermm black, abdomen piceous; rostrum pale ochraceous, the basal joint black; legs pale ochraceous, the anterior femora, apices of intermediate and posterior femora, apices of all the tibiæ, and apices of the anterior tarsal joints black; head somewhat coarsely punctate on basal area; pronotum finely and sparsely punctate on the smooth anterior subconvex lobe, more coarsely so near the anterior margin, posterior lobe thickly coarsely punctate; scutellum finely punctate, the apical area with an obscure
central, longitudinal, cirinate line ; corium somewhat evenly and regularly punctate ; sternum more or less coarsely punctate, the three ultimate abdominal segments finely irregularly tuberculate.

Long. 10 mm .
Hab. Burma; Karennee.
Usilanus denotatus, sp. n.
Piceous black; less than basal half of pronotum and anterior and lateral pronotal margins (narrowly), clavus and corium, lateral margins (narrowly) of sternum and posterior lateral angles of prosternum, abdomen beneath, first and second joints of antennæ (remaining joints mutilated in type) castancous brown; rostrum and legs ochraceous, basal joint of rostrum and the anterior femora castancous brown ; margins of the clavus paler; imer apical area to corium piceous, containing two small pale spots (one at its anterior margin, the other on the apical margin) ; membrane fuscous brown; head with the apes of the central lobe prominent ; first joint of antenme considerably shorter than second; rostrum with the first joint slightly passing base of head; pronotum shorter than breadth at base, the lateral margins obliquely rounded, faintly transversely impressed a little behind middle, the basal pale area somewhat coarsely punctate, the posterior angles margined with piceous, the posterior margin moderately concavely sinuate ; scutellum sparingly punctate, more strongly punctate along the lateral margins; clavus longitudinally punctate ; corium more irregularly punctate; membrane slightly passing the abdominal apex; anterior femora obtusely spined beneath.

Long. $9 \frac{1}{2} \mathrm{~mm}$.
Hab. Burma; Bhamo.
Lua, gen. nov.
Head about as long as breadth between eyes, robust, deflected on each side, anteriorly subangularly produced; antemæ robust, pilose, first joint about or almost reaching apex of head, second joint a little longer than third, third and fourth subequal in length ; rostrum reaching the intermediate coxæ, first joint about reaching base of head; pronotum nearly twice as broad at base as long, with a strongly punctate anterior collar, the basal area also strongly punctate, lateral margins carinate, convexly rounded towards the eyes, anterior margin truncate, posterior margin a little concave before scutcllum ; scutellum about as long as broad at base,
where it is a little gibbous, laterally deflected on each side, somewhat coarsely punctate; hemelytra not reaching the abdominal apex, membrane very small and ill-defined, lateral margins a little widened beyond middle and then obliquely narrowed to apex, clavus very coarsely longitudinally punctate, the disk sparingly coarsely punctate ; body beneath and legs pilose; legs of moderate length, the femora moderately and uniformly thickened.

Allied to the Neotropical genus Rhaptus, Stal. Judging from the description, it also possesses some resemblance or affinity with Lispochroa, Bredd., but from this genus (?) is distinct by the shorter hemelytra.

## Lua tartarea, sp. n.

Body above and bencath shining black ; anternæ and legs pale ochraceous ; apical joint of antennæ and base of first joint piceous; femora (excluding apices) more or less pale castaneous; head between the eyes smooth and shining, remaining area punctate; pronotum with the basal area coarsely punctate, before which it is obscurely transversely impressed, between this impression and the anterior punctate collar the surface is smooth and shining; scutellum punctate, the basal area smooth and shining, between which and apex is an obscure central longitudinal line; corium punctate as described in generic diagnosis, an obscure pale brownish spot on each side of clavus near apex of scutellum and a similar subcostal spot on corium a little beyond base; membrane short, indistinct, dull brownish ochraceous, not reaching apex of abdomen; sternum irregularly punctate beneath, as shown in figure.

Long. 3 mm .
Mab. Ceylon; Nalanda (Green) ; Minikoi (Gardiner).
In the Minikoi specimens the spots to the corium are much brighter than in Ceylonese type, and the extreme lateral margins to the pronotum (sometimes) and the posterior lateral pronotal angles (frequently) are ochraceous.

## Atkinsonianus, gen. nov.

Head about as long as broad at base, subangularly produced and narrowed before the insertion of the antenne; ocelli near eyes ; antennæ with first joint shorter than head, second joint longest, third and fourth subequal in length; rostrum reaching the intermediate coxæ, first joint not quite reaching base of head, eyes not quite reaching the anterior
angles of the pronntum ; pronotum somewhat flat, broader than long, a little narrowed anteriorly, with a very slight or subobsolete transverse impression near middle, a short longitudinal ridge near the posterior lateral angles, the lateral margins very narrowly ampliate and very slightly sinuate, rounded at anterior angles, anterior margin truncate, posterior margin moderately concavely sinuate; scutellum about as long as broad, not impressed; corium laterally convexly rounded and considerably wider than the margins of the pronotum; membrane not reaching tho abdominal apex, with strong reticulate markings giving the appearance of reticulate venation; legs simple.

Near Abdolominus, Dist.

## Atkinsonianus reticulatus, sp. n.

ITead, anterior area of pronotum, and the scutellum black or piccous, antrrior and lateral margins, and posterior area of pronotum castaneous brown, on the subimpressed line dividing the dark and pale pronotal areas are three paler spots ; clavus and corium pale ochraceous, thickly brownly punctate, in some places macularly punctate; membrane subhyaline, reticulately spotted and marked, and with prominent black spots at the basal margins; body beneath black or piceous, margins of the sternal segments, rostrum, coxæ, legs, and apical area of abdomen more or less castaneous; head with the apical area finely granulose, the base almost smooth; pronotum thickly finely punctate, with three more or less developed longitu linal grooves; scutellum thick!y punctate; other characters as in generic diagnosis.

Long. $5 \frac{1}{2} \mathrm{~mm}$.
Hub. Silhim (Atkinson Coll., Brit. Mus.).

## Gonsalvus spinosus, sp. n.

Head, pronotum, and scutellum black; apex and a more or less developed median line to central lobe of head ochaceous; antennæ piceous or black, basal half of second joint ochraccous, fourth joint greyishly pilose; body beneath and femora black or piceous; rostrum, tibiæ, and tarsi ochraceous or brownish ochraceous; corium dull ochraceous, clavus with longitudinal black lines, corium blackly punctate, the punctures more or less arranged in longitudinal series; membrane piceous, the veins much paler ; antennæ with the first joint scarcely half the length of second, which is slender at base and slightly longer than third, fourth slightly shorter than
third; head impunctate, the ocelli at base and near eyes; pronotum with the anterior lobe tumid, impunctate, the lateral margins moderately convex and narrowing to head, posterior lobe sparingly coarsely punctate ; scutellum sparingly finely punctate; anterior femora incrassate, finely spined beneath, the anterior tibiæ moderately curved and strongly inwardly ampliated at apices ; membrane slightly passing the aidominal apex; rostrum reaching the posterior coxa.

Long. 6-7 mm.
Hab. Calcutta.
Differing from $G$. typus, Dist., by the spinous anterior femora and the more dilated apices of the anterior tibio, different colour of the legs, \&c.

This species was taken at light in November 1907.

## Correction.

In Faun. Brit. Ind., Rhynchota, vol.iv. p. 432, I described the genus Armatillus and unaccountably included it in the Pentatomidæ. This was a wrong location, and it should have been placed in the Pyrrochoridæ. I have to thank Dr. Bergroth for calling my attention to this very obvious tasonomical misplacement.
XLIII.-Descriptions of Four now Species of Heterocera from I'ropical South America. By Herbert Druce, F.L.S. \&c.

## Fam. Limacodidæ.

## Langucys nigropuncta, sp. n.

Femule.-Head, antennæ, collar, tegulæ, and thorax black, the base of the thorax red; abdomen black; legs black, spotted with white. Primaries black ; the costal margin, a submarginal band, and a line crossing the wing near the base all red; a row of black spots edged with red crosses the wing abont the middle, the fringe white : secondaries black, with a large red spot at the apex; the costal margin red, the fringe white. Underside very similar to the upperside, but rather paler in colour.

Expanse 13 inch.
Hab. W. Colombia, San Antonio, 5800 feet (G. 1/. Palmer, Mus. Druce).

This species is allied to Langucys nigrorufus, Walker.

## Fam. Noctuidæ.

## Subfam. Hadenines.

## Miselia ruflinea, sp. n.

Mate.-Head, antennæ, palpi, collar, tegulæ, thorax, and legs dark brown; abdomen black. Primaries dark brown, indistinctly spotted with darker brown; a submarginal red line extends from the apex to the anal angle; the fringe dark brown: secondaries black, becoming greyish at the base. Underside blackish brown.

Expanse $1 \frac{1}{2}$ inch.
IIab. S.E. Peru, Santo Domingo, 6000 feet (Ockenden, Mus. Druce).

## Subfam. Acronyctind. <br> Gonodes obliqua, sp. n.

Mate.-Head and antennat brown, collar and tegule pinkish grey, thorax and abdomen pale brown, anus yellowish, legs pale brown. Primaries pale brown, with a pinkish shade over the basal half of the wing, slightly irrorated with black scales; a fine reddish-brown line crosses the wing from about the middle of the costal margin to the anal angle; near the apex are two very fine white lines partly crossing the wing; the fringe brown: secondaries very pale whitish brown, with a dark mark at the end of the cell and a submarginal brown line extending from the apex to the anal angle ; the fringe pale brown. Underside pale pinkish grey, marked very similar to the upperside.

Expanse $1 \frac{1}{4}$ inch.
Ilab. Colombia, Minca, 2000 feet (II. II. Smith, Mrus. Druce).

## Emarginea niphoplaga, sp. n.

Female.-Head, collar, and tegulæ greenish white; thorax and abdomen black, with some white hairs at the base ; the underside of the abdomen white; legs black, spotted with white; antennæ hlack. Primaries greenish white, broadly shaded with brown across the middle of the wing; a large white spot on the costal margin, beyond which several fine waved black lines cross the wing from the costal to the inner margin; the apex is white, the fringe black: secondaries white, with a faint submarginal black line extending from the apex to the anal angle.

Expanse 1 inch.
Hab. Colombia (Mus. Druce).
XLIV.-Descriptions of Three new Species of Heterocera from Dutch New Guinea. By Herbert Druce, F.L.S. \&e.

## Fam. Arctiidæ.

Diacrisia arctichroa, sp. n.
Female.-IIead above and collar cream-colour ; tegulæ black, edged with cream-colour ; antennæ, palpi, and thorax black; abdomen above bright red, with a central band of black spots; underside yellow, with a double row of black spots on each side; legs and underside of the thorax black; anus yellow. Primaries dark cream-colour; three black spots on the costal margin; a large square-shaped spot at the bottom of the cell; a black dot close to the base; a large spot at the end of the cell; a row of black spots of various sizes crosses the wing from the apex to the middle of the inner margin and two black spots at the anal angle; the fringe cream-colour: secondaries bright red, with a double series of black spots close to the anal angle, and several black dots near the apex. Underside similar to the upperside, but darker in colour ; the primaries are clouded with red and the ground-colour of the secondaries is chrome-yellow; the black markings are the same as above.

Expanse $2 \frac{1}{2}$ inches.
Hab. Dutch New Guinea, Fak Fak, 1700 feet (E. A. Pratt, Mus. Druce).

## Fam. Notodontidæ.

## Nadata gigantea, sp.n.

Male.-Head, collar, tegulx, and thorax orange-red; palpi and antemæ pale brown; abdomen pale reddish brown; the underside pale brown; legs blackish. Primaries orange-red at the base, shading to brown and yellow to beyond the middle of the wing, the outer margin broadly bordered with darker brown ; a black dot at the end of the cell ; six pale brown waved lines cross the wing from the costal to the imer margin; the fringe dark brown: secondaries orange-red, brownish round the outer margin; the fringe dark brown. Underside: both wings pale yellowish brown, with a submarginal row of brown spots extending from the apex to the inner margin of both wings; the primaries shaded with pink at the base; the fringes as above.

Expanse $5 \frac{1}{4}$ inches.
Hab. Dutch New Guinea, Fak Fak, 1700 feet (E. A. Pratt, Mus. Druce).

Fam. Noctuidæ.

## Subfam. Quadrifinza.

## Pterocyclophora pratti, sp. n.

Male.-Head, palpi, antennæ, collar, and tegulæ dark brown; thorax and base of the abdomen grey; abdomen above dark brown; the underside and legs pale greyish brown; the anus fawn-colonr. Primaries dark purplish brown, broadly bordered with fawn-colour on the outer margin fiom the apex to the anal angle, the apex broadly suffused with purplish grey; an elongated fawn-coloured spot at the end of the cell; a small white dot close to the lase, the inner margin edged with white ; the fringe fawn-colour: secondaries bright yellow; a blackisk-brown band irrorated with purplish-brown scales extends from the anal angle almost to the apex, the outer margin purplish grey. Underside: primaries fawn-colour, thickly irrorated with brown and black scales ; the basal haif of the wing pale yellow, two distinct black bands crossing the wing, but neither exiending to the costal or imer margin ; a marginal row of black spots extends from the apex to the imer margin : secondaries pale fawn-colour, irrorated with brown scales and crossed by three black lines.

Expanse $2 \frac{3}{4}$ inches.
Hab. Dutch New Guinea, Fak Fak, 1700 feet (E. A. Pratt, MLus. Druce).

This species is allied to Pterocyclophora pictimargn, Hampsn., from Ceylon.
XLV.- On Mammals collected by Ni. S. A. Teave, M.A., b.Sc. (Oxon.), in Katunga, Congo Free Stute. By Ciuy Dollman, B.A.

THe collection is of interest both on account of the new gengraphical ranges established for many of the species and, in addition, for the discovery of a new form of Anomalurus allied to $A$. cinereus, 'Thos.

## 1. Eidolon helvum, Kerr.

\&. 99. Lufira River.

## 2. Epomophorus zenkeri, Matsch.

ठ. 1; ㅇ. 28. Kambove.
"The fivit-cating bats, whel are mot uncommon, especially in the well-wooded districts, are called by the natives 'Mulima' or 'Kamlima.'"

## 3. Scoteinus schlieffeni, Peters.

ठ. 32; + . 33. Katanga.
ठ. 47 ; \%. 48. Upper Lufira River.
"Small bats are called 'Kasasusu" by the matives in Katanga, a name sometimes also applied to butterties."

## 4. Petrodromus sp.

б. 49 ; ㅇ. 18. Katanga.

Iu size and general proportions similar to $P$. tetradactylus, Peters, but differing from that form in having a more hairy tail and in the absence of any buff-coloured tint on the under surface.

Probably these Katanga specimens are more closely allied to the Nyasaland form, $P$. venustus, Thos., than to the more southern $P$. tetraductylus, though at present sufficient material is not at hand to settle this point.
"(Galle l locally 'Kapata.' An animal which generally frequents the thickets ide. on river-banks in the low comntry. Consequently comparatively scarce in Katanga, which is mostly high plateau."
5. Nasilio brachyurus, B. du Bocage.

ภ. 5 วั ; ํ. 56. Katanga.
6. Nasilio brachyrhynchus, A. Smith.

## ठ. 7; ¢. 2. Katanga.

This species appears to occur in Katanga side by side with $\therefore$. brachyurus. It is, however, possible that the sp cimens identified as $N$. Urachyurus from this region are only seasonal forms of $N$. brachyrhynchus, as both the N. brachyurus were collected in July and the N. Urachyrhynchus in Febsuary. The skulis of the two species are so much alike that it is impossible to decide this question till further specimens are available for examination.
" Generally occurs in hilly and somewhat npen conntry. Native name 'Kalolo.'"

＂Lives in long grass and reeds near rivers．It is called ＇Chimuluwulwe＇by the natives，in imitation of its curious chattering note．＂

## 14．Crossarchus fasciatus，Desm．

․ 44．Near Kambove．
"A very common sprecies, often in large colonies. Native name 'Chipulwe.'"

## 15. Funisciurus annulatus rhodesice, Wrought.

J. 36, 43. Upper Lualaba River. ㅇ. 98. Lufupa River.
" Ustally among large trees. Native name • Mishiuzi.'"

## 16. Funisciurus cepapi, A. Smith.

ơ. 23, 37. Katanga.
"Frequents thin woodland ; is not common. Native namo 'Kampandwa.' "

## 17. Anomalurus neavei, sp. n.

d. 52. Kambove, Katanga.

Size as in $A$. cinerens, Thos., but with much smaller scale; on the base of the tail, smaller feet, and the fur more buffcoloured.

General colour of back grey, washed over with buff. Under surface distinctly buffy. Individual hairs of back slate-coloured, with light yellowish rings at tips. Upper surface of forearms and hands light buffy. Upper surface of feet, including hairs covering claws, greyish buff. In A. cinereus the claws are covered with long black hairs, sharply marked off from the grey hair on the backs of the feet. Upperside of tail greyish buff for the basal half; posterior portion, comprising a little more than half the total length, dark brown.

Scales on underside of tail small, on an average measuring 7 mm . each in length. In $A$. cinerous the scales are much larger, averaging about 12 mm . long. In the Katanga form the whole scaly area is only 55 mm . long, while in $A$. cinereus it extends much further down the tail, the total length being nearly 80 mm .

The skull exhibits a few well-marked characters that distinguish it from A. cinereus:-Nasals shorter and palatal foramina not extending back beyond the maxillo-premaxillary suture, while in the other form these foramina are prolonged back beyond the suture for about 1 mm . The cheek-teeth are set so that the two rows converge towards one another anteriorly, not being so parallel as in A. cinereus. The teeth are also smaller, the whole tooth-row measuring 1 mm . less in length.
Dimensions of the type (measured in flesh) :-
Head and body 287 mm ; tail 222 ; hind foot 47.5 ; ear 37 .

Skull：greatest length 52 ；zygomatic hreadh ：36；length of upper molar series 12.5 ．

Hab．Near Kambove，Katanga．
Type．Adult male．B．J1．no．7．12．13．37．Collected 27th June， 1907.

This species is sharply marked off from the Nyasa form， A．cinereus，firstly，by its much smaller tail－scales，and， secondly，by the general buff coloration of the fur and absence of black hairs on the claws of the hind feet．

In addition to the type specimen，the Museum possesses two other representatives of this species，an adult female collected by Mr．Neave at Ndola in 1905，and a further specimen collected by Mr．Donald MacDonald in North－ eastern Rhodesia，west of Madona．
＂This animal is not common，and owing to its entirely nocturnal habits is very seldom scen．All the individuals I have met with have been obtained from hollow trees，where it seems to spend the day．＂

XLVI.-Notes on Locomotion and the Use of Slime-threats in
the Marine Mollusca. By Nathaviel Colgan, M.R.I.A.

Whime engaged last year in studying the Nudilmanch fauna of County Dublin the writer of these notes was induced to make some observations on the locomotive powers of certain species of marine Mollusca chiefly belonging to the Gastropoda, and as the results arrived at appear to be in some respects sufficiently novel to merit permanent record, they are set out here in some detail. In all 18 species were dealt with, 10 Prosobranchs, 7 Opisthobranchs, and 1 Filibranch, and the aim of the inquiry was not so much to determine the rate of travel of the various species as to ascertain whether any of them were accustomed to make use of suspensory slime-threads as an aid in locomotion.

Every student of the marine Mollusca is familiar with the fact that the Gastropods in general have a strong propensity to float font upswards on any still-water surface they may be enabled to reach by crawling, and that many of them are accustomed to suspend themselves beneath that surface by means of slime-threads or attenuated strings of the mucus which all of them so freely secrete. But hitherto observation does not appear to have very conclusively established the fact that the power of re-ascending by such threads to the water surface is possessed by many of our native species of marine Mollusca. H. Wallis Kew, indeed, in his well-known paper on Spimning. Molluscs in the 'Zoologist' for July 1900, states
that " most spinning Pectinibrancls no doubt are able to ascend to their former positions by crawling up the suspensory thread: this has been observed in Litiopa, in Valvata, and perhaps in Rissoa." The reference to Rissoa in this connexion is apparently drawn from Gray's account of the behaviour of Rissoa parva given in 1833 to the Zoological Society of London, where he states that the animal "has the power of emitting a glutinous thread by which it attaches itself to floating sea-weeds and is enabled when displaced to recover its previous position." Gray, too, in a later communication, published in these 'Annals' fifty years ago, (3) iv. 1859 , p. 239, appears to attribute the power of re-ascension to the Opisthobranch Elysia viridis; but in this case, as in his note on Rissoa parva, his language is not quite clear.

Of the 18 County Dublin species placed under observation by me last year no less than 10 were seen to climb up along their suspensory slime-threads to the water surface from which they had descended ; and I have little doubt that had material and opportunity been forthcoming for further observation, many others of the 18 would have shown themselves to possess the same power. As for the method of observation adopted, in all cases the living animals were placed in graduated tubes or phials of convenient size filled with fresh sea-water, which was renewed from time to time. For the smaller species tubes 2 inches high by $\frac{3}{4}$ inch in diameter were used, for the larger species phials $\ddot{3}$ inches high by $1 \frac{1}{2}$ inch in diameter, so that all of the individuals dealt with lad ample water surface to float and travel upon. Several of the species were observed to drop, to all appearance voluntarily, from the water surface, and hang suspended beneath it by slime-threads; but in order to shorten the period of observation most of them were induced to assume this position by smartly tapping the bottom of the tube against the table on which it stood. As a rule there was little difficulty in so gauging the force of the tap and of the resultan: jar as to dislodge the animal's foot from the slime-raft on which it had travelied out from the wall of the glass tube without altogether severing its connexion with that raft and causing the animal to sink to the bottom.

In all cases the animal was found to hang suspended from the posterior end of the foot, and the slime-thread by which it lhung, fine and diaphanous though it was, could usually be detected by holding up the tube and examining the water with a hand-lens, while varying the strength of the light and the direction of its incidence on the tube. The graduation of the tubes and fluids was effected by narrow strips of white
paper gummed vertically along the outside of the glass ant divided to eighths of an inch by heary hlack lines clearly visible through the water, the white strip throwing out into relief the animal hanging suspended in front. The scale thus served to measure the rate of ascension of the animal, whether along its suspensory thread or in the more usual mode of locomotion along the glass wall of the tube.

With these few words on the method adopted, details will now be given as to the behaviour of the species observed to climb by their suspensory threads.

Runcina hancocki, Fonbes.-Several specimens w re collected at low water on the shore near Bullock Habom om the $16 \mathrm{th}_{\mathrm{M}}$ May last. One of the largest of these, mearly $\frac{1}{4}$ inch long when in motion, was transferred to a graduated glass tube, and while floting on the water surface was caused by a gentle tapping of the tube to sink to a depth of half an inch and hane there hey its mocons thead. In two minntes it had regained the water surface, the font end of the foot being again and again lorought into constact with the thread, so as apparently to grip it.

Limapontia nigra, Johnston.-()ne of several specimens collected at low ide near Bullock on the 2nd May last was observed on the 4 th to mount a short way by a suspensory thread, but failed to reach the surface. Further particulars of this abortive attempt will he fund farther on in the paragraph dealing with Rissoa cingillus.

Doto coronata, Gmelin.-A specimen of this rather common species dredged at Malahide on the 16th June last was ouserved on the same day to ascend by its thread from a depth of 1 inch in two minutes, the front of the foat during the operation being curled up and applied to the thread.

Eolis farrani, Ald. \& IIanc.-Two specimens of this interesting species, which has its locus classicus at Malahide, Co. Dublin, where it was first discovered by Alder in 1814, "ere captured on Zustera-beds at Shemmick's Island, Skerrier, last year, one on the 1st and the other on the 18th July. The tirst secimen was seen to mount by its suspensory thread to the surface of the water from a depth of 1 inch in the space of one mintute; the second specimen mounted by its tiread in two minutes from a depth of 1 inch and a half. During the ascension the fore end of the foot was from time to time brought into contact with the thread, whle the tentackes and papillæ kepi up a vigorous motion.

Eolis drummondi, Thompson.-One of several fine apecimens fully 1 inch long, dredged at Skerries, was transferved to a phial of sea-water on the 24 th of July last. This was an extremely lively animal, its tentacles and numerous slender papillæ being in perpetual serpentine motion. Mounting rapilly to the water surface, it floated there foot upward until a gentle tap of the phial disengaged it and left it suspended from its slime-thread 2 inches below the surface. With what must have been a strenuous muscular effort the animal, while thus suspended by the tip of its slender tail, brought its head, or, rather, the fore front of its foot, again and again into contact with the slender suspensory thread, and vigorously workiug its tentacles and bristling papille in such a way as to render exact observation of its climbing method impracticable, it regained the water surface and resumed its floating position there in the space of one minute. 'Though the precise method of climbing was not perceptible, the ascent was clearly effected along and by means of the thread and by the application to it of the fore part of the animal's foot.

Skenea planorbis (Fabricius).-This diminutive species; appears to be peculiarly addicted to the use of the suspensory thread both fir descending from and ascending to the water surface, and though its absolute rate of progression is slow, yet in comparison with the size of the animal it is guite rapid. sienea climbs by its thread fully four times its own length in one minnte, while the much more swiftly moving Eolis drummondi accomplishes only twice its own length in the same time. Many specimens of Slierea collected at Bullock were placed under olservation on the 19th April last, and several of these were seen to mount by their suspensory threads, the quickest rate of climbing being half an inch in two minutes, while the average of a number of such climbs by different individuals was found to be 1 inch in six minutes.

As with all the other species observed, the foot and tentacles of Skenca were in constant vigorous motion while the animal mounted by its thead to the water surface. Again and again one or other of the many floating individuals was seen 10 lower itself by its thread for $2 \frac{1}{2}$ inches. On one occasion an indıvidual having lowered itself by a series of jerky drops almost to the bottom of the tube, remounted one-eighth of an inch along its thread befure it finally resumed its descent and rached the bottom ; another, having descended in the same manner, remounted its thread for half an inch, or, say, for eight times its own length.

The slime-thread in this, as in all the species observed, was distinctly elastic. When one of the floating animals was gently pushed outwards by a needle-point from the side of the glass tube by which it had ascended, it would spring backwards towards the side as soon as the needle was withdrawn. The thread or film was evidently continuous along the side of the tube and over the water surface to the point where the animal floated. This was more than once made apparent in this way :-An individual fl ating quite close to the side of the tube would drop and suddenly come to rest about half an inch below the water surface and against the side of the tube. If tha tulse were then quickly moved from a vertical to an almost horizontal position the animal would be found hanging suspended across the tube from a point in the side. This suspension was evidently from a portion of the slime-thread formed by the animal in ascending, as the change of position of the tube was effected so guickly as to prevent the animal applying its foot afresh to the glass surface, and so producing a new attachment and a new thread.

The peculiar jerky method of deacent by its slime-thread frequently observed to take place with this species appears to me to negative the idea that such motion is accidental or involuntary, as has been suggested by G. Sheriff 'Tye * and II. Wallis Kew $\dagger$ in their well-known papers on the subject of thread-spiming in the Mollusca. The abrupt pauses in and resumptions of the downward motion of Shenea appear to me to be explicable only on the assumption that the animal while descending, voluntarily and at intervals, inhibits and sets in action the discharge of mucus-in other words, that it makes its suspensory threal of set purpose. The appearances are inconsistent with an accidental lengthening of an clastic film, caused by the animal suddenly losing its foothold on the water surface, and so throwing its weight on that film at one point.

Rissoa striata (Adams).-This rather sluggish species, as it proved to be, was observed several times on the 1st May last to drop from the water surface and hang suspended by its thread. On one occasion the thread was seen to issue from the edge of the closed operculum, as if the animal had released itself from the water surface on which it crawled by withdrawing its foot. One individual was seen to mount its thread for three-quarters of an inch in two minutes, the

[^54]motions of the foot during the process being similar to those obscrved in the species already mentioned.

Rissoa parva (Da Costa).-Several specimens of this very common littoral species were placed under observation on the 29th April last. It proved to be more active than its congener $R$. striata. Again and again, when by smartly tapping the tube a floating individual was caused to sink below the surface on its suspensory thread, it was seen to regain its floating position by climbing up the thread. On one occasion the anterior part of the foot was observed to be brought into contact with the thread as the animal ascended, and the water surface was seen to be drawn downwards into an inverted cone at the point of suspension. The quickest rate of thread-climbing observed in this species was half an inch in one minute.

Rissoa cingillus (Montagu).-A single specimen of this species along with six specimens of Limapontia nigra, all gathered in rock-pools at Bullock on the 2nd May last, were placed two days later in a glass tube of the usual dimensions, 2 inches by $\frac{3}{4}$ inch. In a short time all of the animals had crawled up the side of the tube and assumed the floating position foot upwards on the water surface. The tube was laid aside for a short time, and when the observation was resumed the Rissoa was found suspended by its thread at a depth of $\frac{7}{3}$ inch, and vigorously working its foot and tentacles as if engaged in climbing. Half of the Limapontias were missing, only three of the six placed in the tube being visible on the surface. On holling the tube against the light and bringing a hand-lens to bear on the suspended animal I found that the three missing Limapontias had attached themselves to the shell of the Rissoa, which was striving hard to lift itself and its living burden to the surface. Although one of the Limapontias was fully as large as the Rissor, hardly three minutes had elapsed before the Rissoa had climbed up three-eighths of an inch. At this juncture one of the smaller Limapontias set out climbing the thread in advance on its own account. It had mounted only a short way, however, when it fell back on the Rissoa's foot, and so hampered its action that the animal soon gave up its laborions effurts to reach the surface and sank slowly with its burden to the buttom of the tube.

Modiolaria discors (Limé).-This common species,
often found swarming in its juvenile state in the littoral zone, of the Dublin coast, is the only Pelecypol whose habits of locomotion I have ohserved. A number of young individuals collected at Bullock on the 21st April last, and averaming $\frac{1}{8}$ inch in the longer diameter of the shell, were found to be expert climbers. Their method of climbing to the water surface, thongh in principle no doult the same as that employed by the Gastropods, was utterly different in appearance. Instead of momiting the tube with an even cliding motion whoze phases eluded observation, the young ILodinlarias hoisted themselves hy intermittent and violent muscular contractions of an inordinately long font, whose tip was anchored in advance of the animal, no doubt by a stiff mucus, as a preliminary to each upward lift of the animal and its shell. Watched with a hand-glass this operation conveyed a grotesque suggestion of a sailor climbing a rope hand-overhand.

When halfway to the water surface one of the individuals, having withdrawn its foot completely into its shell, was seen, notwithstanding, to maintain its position on the side of the tube. A close scrutiny showed that the animal was fixed by a single delicate hyssus thread neatly soldered to the glass by a terminal expansion. Before long I had the pleasure of watching the operation of byssus-making groing on. The animal's foot was protruded to full length beyond the anterior end of the shell near to where the byssus-thread was fixed. For some scconds the font was worked to and fro over the glass and then quickly withdrawn, when a second byssusthread was seen to be fixed in position. After an interval of about a minute the foot was again shot out to full length, this time from the posterior end of the shell. Then for nearly lalf a minute the tip of the fout kept working over the side of the tube in a nervous, hasty, irresolute fashion, fumbling, in fact, and when it was at length withdrawn left three radiating byssus-threads fixed by their knobbed extremities to the glass.

In addition to the power of spinning a byssus, which it pessesses in common with all the Mytilida, Modiolaria discors can produce a suspensory slime-thread and employ it in climbing. On the 2th April last one of many specimens left floating on the water surface in a tube was found to have lowered itself by a slime-thread to a depth of $\frac{3}{4}$ inch. When watched this individual was seen to climb slowly up its thread by applying to it the tip of its long foot, the whole ascent bcing made in four minutes.

The foregoing observations are, perhaps, sufficient to show that the practice of climbing by suspensory theeads attacheel to the water surface, or, rather, to the mucous film supported by that surface, is quite usual amongst the littoral or shallowwater species of our marine Gastropods. Though the difficultics in the way of observing the motions of animals usually minute, and in all cases in violent action on an almost invisible thread, were too great to enable me to demonstrate the precise method of climbing adopted in any of the cases here recorded, there can be hardly any doubt that it was essentially the same as that described by Taylor in the following passage from his 'Monograph of the Land and Freshwater Mollusca of the British Isles.' Speaking of the well-known climbing halit of the land-slug, Limax arborum, he says (page 318) :"The samo mucous filament can also bo made use of if necessary to re-ascend to the point of suspension, this being accomplished by bringing the extremities of the body together and transferring the point of attachment of the suspensory filament from the tail to the head."

The rates of vertical travel up the sides of the graduated glass tubes of 16 out of the 18 species placed under observation were noted with some particularity, and a brief résumé of the results may be given here. 'Taking 1 inch as the standard distance, and giving to each species its quickest observed rate of travel, they may be arranged in order of slowness as follows:-First come Rissoa striata, R. parva, and Modiolaria discors, each crawling its inch in 3 minutes; Trochus tumidus, Slenea planorbis, and Polycera lessonii come next, each with 2 minutes to the inch; then Cyprea europeca, with $1 \frac{1}{2}$ minute, Littorina obtusuta, $1 \frac{1}{3}$ minute, and Rissoacingillus, $1 \frac{1}{7}$ minute. Next we have Trochus zizyphinus, Limapontia nigra, and Actconia corrugata, each with 1 minute to the inch, closely followed by Nassa incrussuta, with 50 seconds. The elegant little Trochus helicinus takes only 35 seconds, and last and quickest of all come Eolis farrani and E. drummondi, each travelling at what may be accounted a dizzy rate $f x$ a maine Gastropod, accomplish an inch in 15 seconds and 13 seconds respectively.

All of these rates are rates of climbing rather than of simple travelling, since they were made on a vertical surface of smooth glass, and no doubt were considerably slower than the rates for the same species would have been on a horizontal surface. Taylor, iu his Monograph already quoted from, has been pleased to calculate the mileage rate of several land and freshwater mollusks. Some of the more active lamd-slurs
he gives a rate of a mile in about 8 days, presumably on a horizontal surface, while Ancylus fluciutilis, he tells us, has been recor led to travel at the rate of a mile in 2 years and 10 months. It seems doubtful whether any of our marine Gastropods will be found to excel Ancylus in the deliberateness of its movements, while it is not improbable that Eolis drummondi, on the level, might be found to rival the speed of the Limaces, since the olservations recorded in these notes show that the Nudibranch can climb at the rate of a mile in about 9 days 18 hours. To compare the small things of the organic world with the great things of the inorganic, the quickest travel rate of $E$. drummondi is some 260 times as great as the summer motion of the central and most rapidly moving portion of that famous ice-stream, the Mer de Glace.
XLVII.-Alcyonarians from the Gulf of Ciutch. By Prof. J. Arthur 'Thomson and Mr. George Crane, B.Sce, University of Aberdeen. (Preliminary Note.)

In the course of an investigation of the shallow-water fama of part of the Gulf of Cutch, Mr. James Hornell made a small collection of Alcyonarians which presents some features of interest. The precise district was the coast of Okhamandal, which forms the N.W. extremity of the Kattiawar Peninsula, and Mr. Homell has called our attention to the fact that specimens of Dendronephetlya (hetter known as Spongodes), of Lophogorgia, \&c. could be collected at low tide.

The collection includes eight species, one of which-Astromuricea stellifera-is new. There is also a new varicty of a remarkable species of Echinomuricea previously found in the Indian Ocean.

The position of the various species may be indicated as follows:-

Order AECYONACEA.
Family Alcyonide.... (1) Scleropluytum polydactylum (Ehrenberg).

Family Nephthirid.玉 .. (2) Dendronophthya (Spongondes) dendra$p h y t a$ (Wright and Studer).
(3) Dendronephthya (Spongodes) brevirama (Burckhardt).

Order AXIFERA.
Family Muriceide.... (4) Astromuricea stellifera, sp. n.
(5) Echinomuricea uliginosa, Thomson
and Simpson, var. tenerior, nov.

Family Gorgoxide.... (6) Lophangorgica lutkeni, Wright and Studer.
(7) Juncella juncea, Pallas.

Order Stelechotorea, Section Pennatulacea.
Family Virgularide.. (8) Virgularia rumphii, Kölliker.
(1) Sclerophytum polydactylum (Ehrenberg) is a wellknown widespread species, previously reported from the Red Sea, Maldives, Gulf of Manaar, China Sea, Zanzibar, British New Guinea. It is characterized by the absence of siphonozooids, the small size of the autozooids, and the tough fleshy texture. The specimens from the Gulf of Cutch were large, the maximum dimensions being 5 cm . in height by 14 in length and 8 in breadth.
(2) Dendronephthya (Spongodes) dendrophyta (Wright and Studer), a species of the flattened umbellate type in Kiikenthal's dendroplyta group, previously recorded from Philippines and China Sea. It is represented by lonsely branched and close-set types of polyparium, as figured by Wright and Studer and by Kükenthal respectively; the anthocodire show the characteristic eight double rows of curved spicules, 4 or 5 in each row ; a trivial feature, noted by Wright and Studer, namely the occurrence of numerous superficial $\times$-shaped spicules on the branches, is very marked. The specimens were collected in the month of December, and they show abundant reproductive bodies-probably sperm-sacs-up to 0.25 mm . in diameter, attached to the mesenteric bands far below the polyp-stalks. Some specimens show a few small polyp-bearing twigs on the top of the stalk below the foliate branches.
(3) Dendronephthya (Spongodes) Zrevirama (Burckhardt), a species of the flattened umbellate type in Kükenthal's forida group, previously recorded from Ćhina Sea and 'Torres Strait. A peculiarly fine specimen has a polyparium $12 \cdot 5 \mathrm{~cm}$. in height, with diameters of 10.5 cm . and 5 cm ., with a very short stalk 1 cm . in height, and root-like attachments of about 6 cm . The anthocodie show the characteristic eight double rows of spindles in chevron, with $5-7$ in each row,
the uppermost projecting slightly. A feature of some interest on several specimens is the occurrence of a number of small twigs on the short stem portion almost down to the level of the stolons, each twig bearing two or three polyps.
(4) Astromuricea stellifera, sp. n.-A reddish, fan-like, flexible colony ( 14 cm . in height by 28 cm . in breadth in maximum dimensions) with very abundant anastomosis. 'Ihes axis is dark glossy brown and almost smooth. The coenenchyma is very rough. The verrucae are crowded on all sides of the asis; they are cylindrical and their apex is fringed by about a dozen projecting spicules: The anthocodis are completely retractile within the verruce ; there is a low, almost horizontal, tentacular operculum ; two colouless converging spindles lie on the aboral surface of each tentacle, and there is a single or double ring at the base of the tentacles; otherwise there seem to be no spicules in the polyps. The spicules of the coenenchyma are (1) irregular warty stars and toothed plates, (2) stout spindles with tuberculate warts, and (3) small irregular borlies-all of a rosered colour. This species differs from the other members of the genus in many details, $e . g$. in the absence of lng needle-like processes on the spicules frirging the mouth of the verruca.

Localitics. Low water at Kiu Okha, and dredged off S.W. coast of Beyt Island.
(5) Echinomuricet uliginosa, Thomson an l Simpson (1909), var. tenerior, nov.-The 'Investigator' collection of littoral Indian Ocean Alcyonarians includes a new species of Echinomuricea (E. uliginosa) which is described in detail by Thomson and Simpson in a memoir just alont to be published. A variety of this species occurs in Mr. Homell's collection. The diagnosis of the species is as follows:-A pinkish-red colony branched in one plane; the conenchyma is thick an:l very rugose, with spicules projecting in all directions; the verruca are thickly disposed, covering most of the surface; their walls bristle with the long smooth spines of projecting spicules; there is an elevated conical operculum composed of two bent spindles which touch for over three-quarters of their length, but diverge near the collaret, the interspace being almost completely filled by a short, curved, transversely disposed spindle; the homy axis is brown, cylindrical, and chambered, firm and flexible beluw, solt and collapsibie above; the spicules include a varity of furms: ( $i$ ) some showing a projecting smooth spine with branching warty arms
at the base; (bi) spindles covered with irregular warts; (c) spindles bearing in addition to warts a number of smooth projecting spines on one side ; (d) irregular forms with warty branches on one side and smooth spines on the other ; (e) bifurcate spindles; $(f)$ irregular plates with warty branches; and $(g)$ smooth spindles in the anthocodiæ.

Locality. Laccadives (Kalpeni Bank) and Arakan coast, 13 fath.

The specimen from Cutch differs from the type in the following particulars:-It is unbranched ( 65 mm . in height, with a diameter of 3 mm .) : it is more delicate in appearance and lighter in colour ; the large pointed spicules surrounding the mouth of the verruca are pink to white, instead of deep red ; the gromid-colour of the coenenchyma is white, instead of red or pink ; the spicules are more delicate and bear longer spines; the superficial spicules of the cenenchyma are white spindles with prominent rough warts, and reaching dimensions of $0.61 \times 0.19 \mathrm{~mm}$, while the corresponding spicules in the type are thick red spindles with short close-set warts, aud of larger size, viz. $0.91 \times 0.23 \mathrm{~mm}$.

Locality. Off Dwarka, 16 fath.
(6) Lophogorgia lutlieni, Wright and Studer.-The representatives of this species are much larger and more copiously lranched than those described in the 'Challenger' Report ; the largest specimen reaches a height of 45 cm . and the main stem has a diameter of abuut 7 mm . The verrucas show cight triangular marginal lobes bent over the retracted tentacles, and it is of some interest to note that while the veruca of some branches stand out to a height of 1 mm ., the openings on other branches are flush with the general surface of the cœenenchyma.

Locality. Off Beyt Island, 3-4 fath.
(7) Juncella juncea (Pallas).-Unbranched and slithtly branched colonies, yellowish white (with a touch of red) to buff in colour, with very crowded verruce without definite arrangement. The spicules are clubs and double stars, intermediate forms between clubs and double stars, and a few single stars. We have referred the specimens to J. juncea rather than to $J$. gemmacea because the former is the older species. Prof. Hickson has suggested that $J$. juncea and $J$. gemmacers should be united in one rather variable species, and a study of various representatives of Juncella has led us to the same

Ann. \& Mag. N. Hist. Ser. 8. Vol. iii. 25
conclusion. We think that J. gemmacea should be merged in J. juncea.

Locality. S.W. of Beyt Island.
(8) Virguluria rumplui, Kïlliker.-We have referred two specimens to this species, although they differ in some obvious features, which appear to us, however, to have only quantitative importance. They agree with $V^{\top}$. rumphii in having close-set pinnules with crowded polyps and with peculiar interlocking on the metarachidial surface, in having vary numerous undeveloped pimules ( $96-120$ on each side), and in many other respects. 'l'hey differ in having 5.⿹-70 polyps on a pimule instead of $40-44$, in showing no distinct siphonozooids (probably because of imperfect fixing), in having a more slender axis, and so on, but they are much nearer to I. rumpluii than to any other species. In their very numerous polyps they suggest $I$. multicalycina, "Ihomson an! Henderson, but the calices of the latter are exceedingly well defined, whereas they are indistinct in those from (Juteh.
XLVIII.-Two newo Species of Gryllacris in the University Museum, Orford. By Dr. Achille (imiffini (R. Istitut) tecnico, Genova, Italy).

I have recently received for identification from the Hope Department, University Museum, Oxford, owing to the courtesy of Professor L. B. Poulton, F.R.S., and Mr. R. Bhelford, a series of undetermined Gryllacidie. In a memoir of some length, communicated to the Sucieta Italiana di Scienze Naturali in Milano at its session of January 31st, 1909, I have described the Afican, Indo-Malayan, and Australian species of this family of Locustmlea in the Oxford Muscum collection. The following accomit treats of the only two Neotropical species in this collection ; the species evidently are new to science, and one (Giryllari is lomystuff) is highly remarkable on account of the extraordinary structure of the apex of the abdomen, and of the external genitalia of the male.

I seize this opportunity to express my sincere thanks to Professor Poulton for pernit:ing me to examine this interenting coliection, and in particular to DIr. In. Shelford for the troubie he has taken in transnitting the specimens to me and in
suplying nee with all the information concerning theen that I required.

## Gryllacris longstaff, sp. n.

Apud Giryllurricien ablutam, Brunn., locanda. Statura modica: testacea nitida; capitis rertice anterius cum fastigio, cura parte supera frontis et cum primis 4 articulis antennarum colore atro, hoe colore pracipue inferius a colore testaceo reliqui capitis bene diviso, maculis ocellaribus nullis; pedibus unicoloribus testaceis, spinulis pedum posticorum fuscis basi pallidioribus; elytris apicem femorum posticorum tantum attingentibus, testaccis, venis venulis' ne conculoribus, leviter pallidioribus; alis albido-hyalinis, venis venulisque albidis.
0 . Abdomine segmentis dorsalibus brevibus, excepto ultimo abnorme permagno, cujus lateribus inflatis pasterius subtusque magis productis; parte supera hujus segmenti posterius in medio lobum supraanalem perlongum, retrorsum versum gerente, hoc lobo basi petiolato, dein laminam magnam sub,triangularem angulis rotundatis, lateribus et margine pnstico deflexis, apicem cercorum tegentem, efficiente; parte postica magni segmenti ultimi abduminis sub lobo ample excarata; lateribus initeris eiusdem sergenti in appendices cerciferas magnas bicornutas posterius inter se cruciatas, retrorsum et sursum versas, partim a lobo supraanali tectas, productis; lamina subgenitali transversa, marsine postico latissime sinuato, lobis ommino lateralibus posterius versis, apive angustis, stylos breves depressiusculos, apice rotundatos, gerentibus, rel (forsan per exceptionem) interdum stylis destitutis.

Halitat. Jamaica.
Typi: 2 ( Musei Universitatis in Oxford) a D. Cx. B. Longstaff anno 1907 collecti et donati.

Typus A (fie. 1, 5, 6), indicationem: "Jamaica, below 50 feet, Portland, Port Antonio, capt. Feb. 26-07" gerens.

Typus $R$ (fig. :2, $3,4,7$ ), indicationem: "Jamaica, abont 2̈ön ft., Manchester, Wahderston, capit. Feb. 7-07, at light" gerens.

Species propter notas sexmales of valde miranda, forsan typus movi gheris sine cognitione of tamen adhue non instituendi.

$$
25 \%
$$

Color testaceo-flavidus nitilus, pulcher; corrus parum robustum.

Caput ab antico visum ovoideum, pronoto minime latius. Occiput et vertex convexa: fastigium verticis rotundatum, articulo primo antennarum parum latins, hujus latitudinem $1 \frac{1}{2}$ non attingens. Frons inferius supra clypeum depressa, precipue utrinque ; sulci suboculares nulli ; clypeus et labrum subelongata.

Occiput pallide testaceo-cinercum. Vertex cum fasticrin verticis, cum fastiçio frontis et cum dimidia (vel fere dimidia) parte supera frontis, colore atro nitidn, sine maculis ocellaribus; hoc colure subtiliter etiam oculos supra subtusque prim circumdante, a colore pallido hene iiviso (seu in colorem. pallidum hand dilute transeunte). Pars iufera coloris atri frontis in medio simuata vel in medio utingue angulo brevi inferius producta. Genæ, dimidia pars infera frontie, cum clypeo, labro, mandibuli*, palpisque, testacea, levitwr nel,ulosa; lahrum interdum leviter fuscius. Articuli 3 primi antennarum toti atri ; articulus quartus atro-fuscus, articuli $5-7$ testacei interdum leviter fusci, cæteri testacei.

Pronotum a supero visum sulquadratum, convexum, robustiusculum, marginibas antico et postico leviter et late rotundatis; sulco antico valliforme hene expresso ; sulculo longitudinali abheriato parum distincto, antice posticeque fossulari; sulco postico nullo seu ante limbum extremum marginis postici sito; metazona nom ascendens. Lobi laterales humiles, subrectangulares, multo longiores quam altiores, parum adpressi, angulis rotundato-truncatis, margine infero sensim sinuato, margine postico subrotundato-verticali, leviter obliquato, sinu humerali nulio (metazona postice minime pro(lucta). Sulcus V-formis et sulcus posticus sat bene expressi ; intervalli gibbulosi. Color pronoti pallide testaceus, nitidus, leviter nebulosus, supra incertissime pallide trivittatus.

Elytra modica, fere lanceolata, apicem femorum posticorum ægre superantia, testacea nitida, venis venulisque concoloribus vel partim pallidioribus, latitudinem maximam mom. $6 \cdot 5$ parum fost medium subattingentia, apice subacute rotundata. Alæ cycloidex, albidc-hyalinæ, leviter roseo tinctie, venis venulisque albidis.

Pedes modici, testacei, imo condylo articulari tibiarum posticarum tantum interdum incerte dilute fusciore. Tibice 4 antica solito modo spinosa, spinis utrinque 4 modice longis, apicem versus longitudine parum decrescentibus. Femora postica breviuscula, basi valle incrassata, apice breviter attenuata sed ibi angustata, subtus margine externo 6-7 spinuloso, margine interno $\&-6$ spinuloso, spinulis apicalibus
fortioribus, fuscis vel tantum apice fuscis, basi pallidis. Tibiæ posticæ superne longe post basim leviter planiusculæ, ibique in utroque margine spinis 4 , apice fuscis, arnatæ; necnon spinis apicalibus solitis instructæ. Tarsi longiusculi, modice lati.

Abdomen concolor, testaceum, nitidum. Segmenta dorsalia ${ }^{\circ}$ ante-ultima inusitate brevissima, præcipue superne; segmentum dorsale ultimum $\delta$ inusitate permagnum, nitidissimum, convexum, utrinque posterius et inferius magis

Inclitut. Insula Sancti Vincentii (WV. Indix, teste Shelford).
Typus: 1 o (Mnsæi Universitatis in Oxford), nomihil læsis.

Inter Gr. eximiam, Karsch, et Gr. exiguam, Br., loeanda.Corpus statura ן arva, parum robustum, testaceo-ferrugineum, jedibus (exceptis intermediis in typo forsan per notam in lividualem saturatius ferrugineis) concoloribus.

Caput unicolor, pallide testaceo-ferrugineum, $a b$ antico visum ovoideum, pronoto modice latius. Vertex nitidus, convesus; fastigium verticis rotundatum, latitudinem $1 \frac{1}{2}$ primi articuli antennarum subsuperans; macule ncellares nullæ. Frons inferius in medio impressa. Organa buccalia, solito modo confecta, et antemæ cum reliquo capite concolora.

Pronotum (in typo læsum) forsan posterius in medio et utrinque dilute fusco pictum, nebulis obliquis; a supero visum subquadratum; margine antico rotundato, sed in medio non producto; sulco antico valliforme, in medio submullo. Lobi laterales parum longiores quam altiores, postice leviter altiores, angulo postico subtruncato, margine postico subverticali leviter retrorsum obliquo, sinu humerali subnullo ; sulci bene impressi, intervalli gibbulosi.

Elytra parum longa, subhyalina, leviter testacen tincta, venis venulisque concoloribus. Alæ albido-hyaline, venis venulisque pallidis.

Pedes testaceo-ferruginei (intermedii fusco-ferruginei). Tiliæ 4 anticæ subtus utrinque spinis parvis $2-3$ preditæ. Femora postica basi crassa, apice breviuscule sed distincte attenuata, subtus margine externo 5 -spinuloso, margine interno 2-3-spinuloso, spinulis in dimidio apicali sitis, apice brevissime incerte fuscis. 'Tibiæ posticæ exiles, fere teretes, superne inermes, vel rudimento tantum spinule unice circiter in medio marginis interni, vel etiam, sub lente, gibbulis quibusdam minutissimis, locum spinularum perpathcarum omnino rudimentalium indicantibus, preditæ.

Abdomen concolor. Segmentum octavum dorsale modice productum ; segmentum nonum productum, parum cucullatum, pusterius in medio bispinulosum. Lamina subgenitalis $\sigma$ verisimiliter subquadrata, apice latiuscule rotundato, margine apicali in medio sat acute exciso.

Genoa,
Feb. 4th, 1909.

## XLIX.- On the N. Austration liats referred to the (iemus Mesembriomys. By Oldfield 'Thomas.

While working out a very distinct new rat from Kimberley, N. Anstralia, sent to the British Museum by Mr. B. H. Woodward, of Perth, I have had occasion to examine all the species referred by me in 1906 to the genus 4 mmomys *, whose name, being preoccupied, has since been altered to Mesenibriomys.

Apart from the group-characters then ilescribed these species are of a very heterogencous nature, and I am now convinced that they should be further divided into thate genera, whose differential characters would be as fullows:-

## I. Mesembriomys.

Ammomys, Thos. l. c. (nec Raf.).
Type Mus hirsutus, Gould.
Size very large. Form normal; feet narrow, fairly long. Thail very long, jerhoa-like, heavily tufted terminally.

Skull large and stout, peenliarly high and heavy in the anterior frontal region, its highest point at or in front of the front edge of $m^{1}$, and its upper profile strongly buwed at this point.

Molars comparatively normal in structure, not specially laminate; inner cusp of anterior lamina of $m^{1}$ situated, as is usual, behind the level of the midule cusp, opposite the gap between the latter and the middle cusp of the second lamina. Lower molars ( $m_{1}$ and $m_{2}$ ) each with a well-marked re-entrant concavity behind, in which a distinct median supplementary cusp is placed.

Species. M. hirsutus (Mus hirsutus, Gould) and M. mitcrurus (Hapalotis macrura, Peters).

## II. Zyzomys.

Genus novum.
Type Mus argurus, Thos.
Size quite small. Form delicate. Tail sleuder or thickened, lightly pencilled terminaliy, not heavily haired.

Skull light and delicate, not howed in the frontal region, its highest point above $m^{3}$.

* Aun. \& Mag. Nat. Hist. (7) xvi. p. 84 (1906). I may take this oplortunity of drawing attention to am important lapous calumi in this paper. Oii p. 83, bottom line, for Conilurus read Notomys.

Teeth as in Ifesembriomys (see figure in original description of Mus argurus *).

Species. Z. argurus with its subspecies Z. a. indutus, Thos.
The delicate slender build of this animal and its low flat skull will distinguish it from the large convex-skulled Mesembriomys, to which, however, in the essential characters of tooth-structure it undoubtedly bears a near affinity.

## III. Laomys.

Genus novum.
Type Laomys woodwardi, sp. n.
Size medium. Form comparatively short. Fur crisp, almost spinous. Feet short and broad. Tail short, thickened basally, tapering, heavily haired throughout.

Skull flattened above, its highest point above $\mathrm{m}^{3}$, its general shape rather recalling that of Leporillus.
'Teeth with the laminæ very distinctly transverse and separated, the inner cusp of each of the two first lamina of $m^{2}$ in line with the middle cusp, so that the transverse grooves between the laminæ are complete, straight, and uninterrupted. The teeth therefore tend towards the distinctly laminate structure found in Plice, mys, Otomys, \&c. Lower teeth also simply laminate, the lamine not or scarcely pinched in at their middle point, and the posterior lamina of $m_{1}$ and $m_{3}$ without any posterior concavity in which a supplementary cusp might stand.

Species. L. wondwardi, sp. n., and L. pedunculatus (Conilurus pedunculatus, Waite). The more extreme of the two is selected as the type.

The species of this genus are remarkable-looking animals, quite unlike ordinary Murilæ, and more suggesting members of the South-American Octodontinæ.

The following is the description of the new species:-

## Laomys woodwardi, sp. n.

A greyish species, with a short, hairy, but untufted tail.
Size larger than in $L$. pedunculatus. Fur peculiarly coarse and crisp, almost spinous. General colour coarsely lined pale greyish, rather paler than "drab-grey." Individually the hairs are pale grey basally (grey no. 8), becoming drab-grey terminally, about half of them with black tips. Under surface white, the stiff bristly hairs white to their bases; line of demarcation on sides not shary ly marked. Lars large, broad, pale grey. Upper surface of hands and

[^55]Lect greyish white, the fingers and toes pure white. Tail short, tapering, heavily hairel throughout, "slate-grey" (arising from a mixture of blackish and white hairs) above, dull whitish below.

Skull markedly larger than that of L. pedunculatus, but of similar shape. Supraorhital edges sharply square, not ridged. Palatal foramina long and narmw. Bulle smaller than in the smaller species.

Molars much larger than in the allied form, but of quite similar structure.

Dimensions of the type (measured in the flesh) :-
Head and honly 167 mm . ; tail 114 ; himd font 29 ; car 21.
Sikull: greatest longth 41 ; ba-ilar length 32.5; zog matic hreadth 21.3 ; mavals 14 ; intermbital lrealth 5 ; palatilar longth 18.7 ; diastema 11.5 ; palatal foramina $S \cdot 3$; lengt! of upper molar series $7 \cdot 2$.

Hel. P'arry's Creek, nea: Wyndham, E. Kimberley, N.W. Australia. Ǎlt. $100^{\prime}$.

Tigne. (Old femate. 13.M. no. 9. ․ 16. 3. Oricinal numbri 2!. Collecten! !ith Octuher, 1905, by J. P. Rogers. Presented lyy the Perth Museum through B. II. Woodward, Esq. 'Two specimens.
"Trapped in a rough stony gorge."-J. P. R.
This species is readily distinguishable from $L$. pelunculutus by its larger size, shorter tail, and greyer colour.
> L.-Nero Species of Paralloxurus, of the P. philippinensis Group, and a new Pagima. By Uldfield liomas.

(Published by permission of the Trustees of the British Museum.)
Mitherto the Palm-Civets of the Philippines, North and South, and of Borneo, have been considered as all belonging to one species, for which the name P. phi'ipinensis, Jourd. (first locality mentioned, Luzon), has been used.

But a comparison of the material in the British Museum shows that the Mindanao animal is materially larger than that from Luzon, that the Borncan one is quite peculiar in colour, and that an additional form of the group occurs in the Tawi-Tawi Islands, between N. Borneo anl Mindanao.

I also take this opportunity to describe the Hainan representative of Paguma larvata.

## Paradoxurus minax, sp. n.

Size markedly larger than in the Luzon $P$. philippinensis, about equalling that of the Indian $P$. niger. General colour miform dark brown, less mottled than in phiipminensis; three broken lines of black spots fairly well defined on the hack. Light frontal band little conspicuous. Crown and barks of cars blackish brown. Limbs, teet, and tail uniformly daık.

Sliull similar to that of phitipminensis, but conspicnously larger thrughout. Theth of the same general rounded shape, the carnassial with a heavy postero-internal ledge.

Dimensions of the type (measured in skin) :-
Head and body 580 mm . ; tail (broken in type, 440 mm . in another specimen of about equal size) ; hind foot 75.

Skull: basal length 98 ; condylo-basal length 105 ; greatest breadth 60 ; length of nasals in middle line 195 ; interorbital breadth 19 ; breadth of brain-case $3 t$; palatal foramina $5 \cdot 5$; patatal lengti $47 ; \nu^{4}$, length on outer edge $\mathrm{S}^{\prime} 4$, greatest diagonal diameter $9 \cdot 6$.

Hab. (of type). Davao, S. Mindanan.
Type. Adult male. B.M. no. 7. 2. 2.6. Original number 766. Collected by M. P. Anderson. Presented by His Grace the Duke of Bedford, K.G.

This species is readily distinguishable from any of the cther species in the neighbourhood by its markedly larger skull.

I also refer to this species the adult and young specimens cullected by Cuming in the Islet of Camiguin, just N. of Mindatiao, which were called "P.zylanicus" (fortunately as a nomen nudum) in Gray's 'List of Mammals' of 1843 *.

## Paradoxurus torvus, sp. n.

Size about as in $P$. philippinensis. General colour dark coppery brown (hetween mummy-brown and vandykebrown), approaching that of the S.-Indian P.jerdoni. Face wholly blackish, without lighter markings, as are also the backs of the ears, the nape to the withers, and the rump. Back with three inconspicuous black lines. Fore and hind limbs and tail blacisish brown. Under surface dark chocolatebrown.

Skull most like that of $P$. philippinensis, the teeth of

[^56]similar rounded character, larger individually than those of $I^{\prime}$. sabanus, the nearest species gengraphically. Posterior edge of palate of the reversed V-shape found in the grmus Puguma, although it is at about the same distance behind the molars as is usual in Paradowurus.

Dimensions of the type (measured in skin) :-
Head and body 490 mm . tail 410 ; hind foot 64.
Skull: basal length 39 ; condylu-basal length 94 ; greatest brealth 57.5 ; length of nasals in middle line 14 ; interorbital breadth 15.5 ; breadth of brain-a ase 33.5 ; palatal length 42 ; palatal foramina 5 ; front of $p^{1}$ to back of $m^{2} 30 ; p^{4}$, length on outer side 8 , greatest diameter $8 \cdot 7$.

Hab. Bangao Island, Tawi- T'awi Group.
Type. Oid male. B.M. no. 94. 9.25.9. Cullected July, 1893, by A. Everett.

Even if the peculiar coppery-brown colour of this Paradoxure should prove to be due in any degree to a melanoid suffusion (and there is no evidence for this suggestion), the continmation of the dark colour of the head down to the withers, the large size of the teeth as compred with those of $P$. sabunus, and the Paguma-like shape of the posterior nares will distinguish the species from any of its allies.

## Paradoxurus sabanus, sp. n.

Size smallest of the group. General colour a peculiar greyish olivaceous tinged with buffy, being far the most distinctly olivaceous of the Paradoxures. The usual lines and spots on the back visible, but not conspicnons or sharply defined. Underside hrown, the hairs broadly tipped with buff or pale tawny. Muzzle, back of ears, and crown black, a variable amount of light greyish grizzling on the foreheal and area in front of the cars. In some specimens there is a complete frontal light band, and in others not. Limbs and tail blackish as usual.

Skull like that of $P$.philippinensis, but the tecth smaller throughout.

Dimensions of the type (measured in skin) :-
Head and body 465 mm . ; tail 360 ; hind foot 68.
Skull: basal length SS ; condylo-basal length 92 ; greatest breadth 57 ; length of nasals in middle line 16 ; interorbital breadth 17 ; breadth of brain-case 32 ; palatal length 42 ; front of $\mu^{1}$ to back of $m^{2} 28.5 ; \nu^{4}$, length on outer elge 7 , greatest diameter 8.4 .

Hab. North Borneo. Type from Spitang.

Type. Ohd male. B.M. no. 93. 3. 4.5. Collected July, 1892, by A. Everett.

Its peculiar buffy-olivaceous colour and small size will readily distinguish the Bomean Paradosure from P. phitinninensis, with which it was united by Blanford.

## Paguma larvata hainana, subsp. n.

Markings particularly prominent. Tail nearly all hlack. Molars large.

Size about normal. Fur coarse and harsh, not nearly so rich as in true lartuta. Ends of dorsal hairs strong huffr. Head-markings very strikingly contrasted, sharply lefined; median white line pure white to between the ears, and then continued, rather less pure, down the nape nearly to the end of the black nuchal area; black bands bordering it on forehead broad, very deep black; supraorbital white spots small, iufraorbital fairly large, sharply detined; anteaural spots small. Chin black, succeeded behind by a well-marked whitish collar. Belly dull brownish white. Hands and feet black. Tail black, all but its basal three inches above and six below.

First upper molar larger than in true larvatu, conspicuously larger than in subsp. taivana; its surface, in the unworn state, comparatively flat, the posterv-external cusp obsolete. (arnassial scarcely or not larg than in lurcute.

Dimensions of the type (measured in skin) :-
Head and body 470 mm . ; tail 425 ; hind foot 76 .
Upper carnassial, length on outer edge $7 \cdot 6$, greatest diameter $8 ; m^{1} 6.8 \times 7.6$.

Hab. Five-Finger Mountains, Hainan.
Type. Immature male. B.M. no. 99. 9. 2. 1. Collecter April or May, 1899, by Mr. John Whitehead.

Dr. Matschie has suggested that the F'ormosan form of P. larvata, P.l. taicona, Swinh., may be the same as the original larvata, but it has not the well-marked whitish collar mentioncd in Hamilton Smith's description and present in examples from the Lower Yang-tse. Its first upper molar is much smaller than in the mamland specimens, in marked contrast to that of the present amimal, in which this tooth is much larger.

## LI.-New Species of Cenmys and Mrmosa from Amazonia. By Oldfield Thomas.

## (Published by permission of the Trustees of the British Museum.)

Among some Amazonian mammals sent to us for determination by Fraulein Dr. E. Snethlage, of the Goeldi Museum, Para, there are examples of a new Cecomys and a new Marmosa, which are here described. The trp: specimens have been generously ceded to the British Maseum by the authorities at Para.

## Qcomys tapajinus, sp. n.

A large species of a rich tawny-rufous colour.
Size about as in the larger members of the group, marmosurus, roberti, and mumore. General colour brightest of all, a rich tawny or cimamon-rufous colour, about equal to the brightest members of the genus Nyctomys; this colour is browner on the head and fore back, richer on the rump and hips, where it nearly matches Ridgway's "fawny," but is brighter and glossier. Under surface white, the hairs of the throat, chest, narrow middle line of belly, and whole of inguinal region white to the roots, those of the side of the belly slaty grey basally; but none the less the passage from the tawny colour of the flanks and the white of the belly is nearly as sharply defined as in OE roberti, not cradual as in murmosurus. Mands and feet greyish white. 'Tail, as usual, long, uniformly brown, finely pencilled.

Skull most like that of CE. roberti, but rather more heavily built; outer plate of zrgoma-root narrower; palatal foramina longer, tooth-row shorter.

Dimensions of the type (measured in flesh) :-
Head and body 126 mm . ; tail 158 ; hind foot 25 ; car 17 .
skull: tip of nasals to front comer of interparietal 286 ; zyomatic breadth 16 ; nasals 11.8 ; interorbital breadth 5.9 ; zy gomatic plate 2.8 ; diastema $9 \cdot 2$; palatal foramina $5.8 \times 3$; length of upper molar series 4.7 .

Iteh. Santa Rosa, R. Tamauchim, right bank of the Upper Tapajoz R.

Thype. Old female. B. M. no. 9. 3. 9. 9. Original number 21. Collected by Fräulein Dr. E. Snethlage.
'Ihis species may be readily distinguished from the other
three equally large members of Cemys by its much richer colour, in marked contrast to its white belly.

In 1906* I formed the subgenus Ecomys for a number of rats which combined something of the external appearance of Rhipidomys with the characteristic palate of Oryzomys; but, as I failed to find any cranial distinction from the latter genus, I only considered it as a subgenus. Now, however, I find that, as is still more marked in Rhipidomys, the outer plate of the anterior zygoma-root is hardly projected forward in front of the upper bridge, while in Dryzomys there is always a strongly marked projection. As the group is undeniably a natural one, easily recognizable extermally, I think this character, slight though it is, will justify our treating Ecomys as a full genus. A list of the known species is published in the paper above referred to.

## Marmosa emilice, sp. n.

Smallest of the known species ; tail excessively long.
Most nearly allied to M. pusilla, Desmo, but even smaller (combined length of three anterior molariform teeth 4.2 mm . instead of $4 \cdot 4)$. Fur soft and fine; hairs of back about 6.5 mm . in length. General colour above dull fawn, the extreme tips of the hairs washed with dark brown. Under surface buffy white (rather paler than Ridgway's crean-buff), the hairs pale to their roots, without slaty bases. Black eye-rings well-marked. Ears rather larger than in MI. pusilla. Hands and feet dull whitish above. Tail nearly twice the length of the head and body, its extreme base only hairy, the remainder practically naked, uniformly dark brown above and below.

Skull much as in M. pusilla. 'Teeth as in that animal, except that the sceator, instead of being fully as large as or larger than the tooth next in front of it, is distinctly smaller, its vertical height from the cingulum being about 0.7 mm . as against 0.9 mm . in the anterior tooth.

Dimensions of the type (measured in the flesh) :-
Head and body 75 mm . ; tail 142 ; hind foot 13 ; ear 16 .
Skull: greatest length 23.5 ; hasal length 21 : zygomatic breadth 13 ; interorbital breadth 42 ; palatal length $12 \cdot 2$; combined length of three anterior molariform teeth 4.2 .

Hab. Para.
Type. Subadult male. B.MI, no. 9. 3. 9. 10. Original number 30. Collected 13th February, 1909, by Fraulem

[^57]Dr. Enilie Snethlage, in whose honour the species is named.

This pretty little opossum, the smallest marsupial of the New World (with the exception of Percmils surai), may he readily distinguish from it: only near ally, M ormosu pusill, Desm., with which I. agilis, Bumm., would seem to hes identical, by its still smaller size, sinaller secator, and much longer tail.

> LII.-Two new Macaques from IV. Java. By Oldfield 'homas and R . C. Whoughton.

## (Published by permission of the Trustees of the British Museum.)

IN a report reently presmed by us to the Zontogical s.eciety on the magnifiepnt coilection of mammals oftained in Western Java by Mr. (f. C. Shortrilge, and presented to the British Museum by Mr. W. E. Balston, the series of Macaque Monkeys is referiel to M. fusciculuris, laft. Now, hwwever, in working ont some mammals sent us by Mr. H. (. Robinson from the Malay Peninsula and Islants, we have enme to the conclusion that these Monkeys are not referable to fuscicularis, but belong to two species, neither of which appears to have a name.

The first of these is a Javan representative of jasciculuris, while the second lias quite a different skull, more like that of the South-Indian M. sinica.

## Macaca mordax, sp. n.

A large-sized macaque of the long-tailed type, rather larger than M. fuscicularis and with larger teeth than in that species.

Fur coarse, 26-30 mm. long on lower lack, 45-50 mm. on shoulders. General colone a coarse mixture of brown and luff. Arms and legs greyer, the grizzling less marked. Checks and lower surface dirty white. 'Tail like back, gradually shading, at half its length, into a grey-brown like that of the arms and legs. A black line across the face above the eyes.

Skull about as in typical fusciculuris, but somewhat larger and wit!! markedly larger teeth. The posterior nares comparatively large.

Dimensions of the type:-
Hicad and body 600 mm . ; tail 610 ; hind foot 155 ; car 43.
Skull: greatest length 124; basal length 90 ; zygomatic breadth 84; palatal length 52 ; longest axis of posterior nares 13.5 ; upper premolar and molar series 33 ; second molar $8.2 \times 6.8$.

Hab. W. Java (type from Tjilatjap; sea-level).
Type. Adult male. B.M. no. 9. 1. 5. 27. Otiginal number 613. Collected 19th October, 1907.

This species is easily distinguished from the typical fuscicularis of Sumatra by its greater size, duller colouring, coarser fur, and, above all, by its much larger teeth.

## Macaca resima, sp. n.

Smaller than the last, with much shorter tail, broad molars, and concave nasal profile.

Fur rather fine and soft, $30-35 \mathrm{~mm}$. on lower back, $50-5.5$ on shoulders. Colour above a coarse mixture of brown and buff, producing a general effect near "isabella-colour." 'The usual transverse black line above the eyes; cheeks dirty white. Arms and legs grey, the former darker, the latter very pale. T'ail almost black at the base, merging into grey distally. Lower surface of body and itil and inner surface of limbs greyish white.

Skull comparatively narrow; orbits and orbital sentum nearly vertical, the latter joining the horizontal nasals nearly at a right angle. Nuzzle more elongate. Posterior masal openings small, markedly so when compared with those of M1. mordax. Molars very broad, as broad as long.

Dimensions of the type:-
Head and body 520 mm . ; tail 360 ; hind foot 135 ; ear t..
Skill : greatest length 123 ; basal length $95 \cdot 5$; zygomatic breadth 75 ; palatal length 55 ; longest axis of posterion nares 11.5 ; upper premolar and molar series $33 \cdot 5$; second molar $8.5 \times 8.5$.

Hab. Tasikmalaja, W. Java. Alt. 1145'.
Type. Adult male. B.M. no. 9. 1. 5. 31. Original number 1219. Collected 18th January, 1908.

The short tail of this species, though proportionally longer than that of any member of the 1. nemestrina group, serves to distinguish it at a glance from M. morduc, its nearest neighbour, while the skull-characters noted above separate it both from that species and from nemestrina and its allies.

Ann. \& Mag. N. Hist. Ser. 8. Vol. iii.

## BIBLIOGRAPHICAL NOTICE.

Catulogue of the Lepidoptera Phalenar in the British Museum. Fol. VII. Noctuide. By Sir Georem F. Hampsos, Bart. Printed by Order of the Trustees. Sro. London, 190s. Pp. xr, 7199. Plates criii.-cxxii. \& 184 Text-illustrations. P'rice: Text $17 \%$., Atlas $13 s$.

Tire seventh volume of this great work, or the fourth of the Finctuide, includes the first of three volumes to be devoted to the subfamily Aeronyetine, and includes deseriptions of $-4: 3$ species, diviled into 96 genera, a considerable number of both genera and suecies being here described as now. The Acrongetine, as here employed, are characterized in Mr. C. O. Waterhouse's Preface * hy the trifid neuration of the hind wing combined with spinelers tibie and smooth eyes not surrounded by bristle-like hairs, and it is the least specialiser of the subfamilies of the Nuctuide Trifine."

How completely the classification of the Noctuide has been revolutionized of late years may be seen by the number of wellknown genera now included in the Leronyctine, but referred by previous authors to Apamidx, Cusmide, Hadenidæ, Amphiprridie, die. Among these we may note the genera Anp,hipyicu, Ilania, Diptrrynia, Truchace, Eupleaia, Perigia, Eremolia, Lapperinu, Trigonophora, Eriopus, and Thectpophita.

But while entomologists may congratulate themselres on living at a time when it is posible for so extensive and elaborate a work to be published, they must nont forget that it has been led up to by the labours of a long series of precions authors, without which its inception and fulfilment would hare been imposible. It may he well to remember that the last complete Catalogue of Mnths by Francis Walker was puhlished by the British Museum in thirty-fire volumes from 1854 to 1566 , and though out of print and out of date at the present time, was of great value when it appeared, notwithstanding numerous defects and errors, if only as a compendium of the then existing literature of the subject. Whether thirty-fire rolumes will now suffice to complete the much more elaborate work undertaken by Sir (i. F. Hampson is hardly to be expected; but we hope the author will succeed in completing at least the groups including the larger moths, in which he has already made such good progress, before the adrance of old age necessitates his resigning the remainder of the work to other hands.

# PROCEEDINGS OF LEARNED SOCIETIES。 

GEOLOGICAL SOCIETY.
February 24th, 1909.—Prof. W. J. Sollas, LL.D., Se.D., F.R.'., President, in the Chair.

The following communications were read:-

1. 'Paleolithic Implements, ete. from Hackpen Hill, Winterbourne Bussett, and Knowle-Farm Pit (Wiltshire).' By the Rev. Henry George Ommanney Kendall, M.A.

Implements are described from the localities mentioned in the title, which lie at heights of 585,576 , and 450 feet abore O.D. respectively. Hackpen Hill forms a ridge of Cbalk ruming north and south, capped by patches of Tertiary clay. Trimmed stones of eolithic nature were obtained from fields ploughed in Drift-gravels, together with abraded Cpper (irecisand chert, quartzite-pebbles, and small flints. The greater number of the flaked stones were found within and near shallow pits excarated in yellow Drift-clays apparently newer than the lied Clay with Flints, exposed at the edges of the larger hulhows. The implements are unabraded, abraded, and striated; some stained brown, some green, others unstained; evidently some are in situ, others were brought with the Drift. Implements taken from the clay are described, and : distinction is made between the palroliths and neoliths obtained from the same surface. The similarity in the mineral condition of the former to palcoliths from Knowle-Farm Pit is pointed out. and both are referred to the Chelléen period.

It is noteworthy that, while implements and flakes are numerous on the top of Hackpen Hill as compared with good, trimmed pieces. ret at this 570 -foot level on the Winterbourne-Bassett plain implements and flakes are very scarce, while trimmed pieces are very numerous, although the lesel of the Wiaterbourne stones is 300 feet lower. Many of the latter, however, have been ecident! rechipped, and are therefore of later date. The Author conclude: that implements of at least three palrolithic periods are fomm? at Knowle, and these three periods may be compared with the C'helléen, Lower Acheulien, and Cpuer Acheulien of Prof. Commont at St. Acheul. Still older implements (possibly earlier Chelléen) seem also to occur.
2. 'Plant-containing Nodules from Japan, considered struct urally in their Relation to the "Coal-Balls" and "Roof-Nodules" of thie European Carboniferous.' By Marie C. Stopes, D.'se., Ph.D.

These nodules are of interest, because of the plant and animal fossils that they contain. The plant-petrifactions are of a tyle
unknown from the Mesozoic, and will be described separately. The nodules are of Cretaceous age. They enclose numerous marine shells and various plant-remains, well petrified. Unlike the 'coal-balls' and 'roof-nodules,' they are not contained in coalseams or in the roof thereof, but occur in a thick series of shales below the coals, which appear to be of Tertiary age. The microscopic aspect of the matrix shows that it is highly granular, unlike the matrix of coal-balls and roof-nodules. Chemically they consist of about (j0 per cent. of carbonates, both lime and magnesia being present, with 30 per cent. of silicates; the large proportion of silicates is an important point of difference from the Carboniferous nodules, In having numerous plant-fragrnents in a single nodule and in the type of petrifaction the nodules are like coalballs; in having marine shells included in the matrix they are more like roof-nodules. They probably represent fragments of tangled debris, which drifted out to sea but a short distance, and then were speedily petrified. The Authoress acknowledges help from the Government (irant Committee of the Royal Suciety in carrying out the research, and also from the Japanese (iovernment, the Imperial Tniversity, and the local Government of Hokhaido, together with the Tunko Kaisha of Hokkaido.

## MISCELLANEOUS.

On some now Steneoscurs from the O.cford Clay of Peterlorought.

## To the Erlitors of the 'Amals and Mayazine of Natural History.'

(ifentlemex, - Since the publication of my paper on the above sulject in the last number of this Magazine (March 1st), a part of the 'Palæontographica' (Bd. 55, Lief. je \& (6) has been issued, containing a memoir by Dr. E. Auer, also on some Steneosaurs from the same horizon and locality. In this the author describes as a new species St. teleosurroides, the form which I named st. leedsi, and as a new variety, st. larteti, var. lolieni, the animal which I regarded as specifically distinct under the name St. durobrivensis.

It seems unfortunate that Dr. Aucr should have been anticipated hy my brief note after he has taken such pains to produce so excellent a memoir.

Cifarles W. Andrems.
17th March, 1909.

[EIGHTH SERIES.]

No. 17. MAY 1909.
LIII.-Descriptions of new Gencra and Species of NerrZealand Coleoptera. By Major T. Broun, F.E.S.
[Continued from p. 233.]

## Group Colydiidæ.

Bitoma picicorne, sp. n .
Slender, elongate, opaque, nigrescent; legs testaceofuscous; antennæ liccous; spariugly clothed with fine variegated setæ.

Head nearly as large as thoras, with ill-defined granular sculpture and greyish or yellowish setze. Eyes moderately convex, with a few short setic which are almost minute spines. Thorax small, subtrmeate, and widest in front, gradually yet a good deal narrowed behind, its sides not at all lobate, not distinctly crenate, but somewhat explanate near the front; there are two very small elevations near the front, it seems depressed along the mirdle, and its gramular sculpture is not easily seen; the setæ are rather short, coarse, and yellowish principally. Elytra elongate-oblong, parallel, evidently wider than thorax at the bave; there is a depression at the middle of the base which is bordered by slight elevations; the suture appears faintly yellow owing to the setre there, the space along each side of the suture seems

Ann. \& Mag. N. Hist. Ser. 8. Vol. iii.
dark or slightly depressed, its sculpture is granular but illdefined; on each near the base there is one distinct white spot, there are two more spots in line with the first, but are not white and distinct : the sculpture near the sides consists apparently of series of granules and linear longitudinal interstices; there are a few minute grey spots noar the apex.

Antenure finely and sparingly setose, basal joint just visible above; second stout, longer than hrod, suboviform but truncate at apex ; third clongate, $4-7$ each rather longer than broad, ninth broader than the preceding one, tenth strongly transverse, eleventh nearly twice as long as the tenth.

Tarsi with rery few fine setie, second and third joints more prolonged underneath than the first, but not lobed, the terminal rather longer than the basal three combined. Tibia straight, finely setose; claws yellow.
B. ruyosa is the only near ally ; it varies from testaceons to rufo-fuscous, and lacks the narrow raised longitudinal interstices of $B$. picicorne, the basal joint of the antemae is more exposed and the terminal one is shorter and more rotundate, and the sides of the thorax are more jagged.

Length $1 \frac{1}{4}$; breadth $\frac{3}{8}$ line.
Broken Raser. One individual from Mr. J. II. Lewis.

## Coxelus elongatus, sp. n.

Elongute, slightly convex, subopaque, concolorous, fusenrufous; antemæ clear red, club piceous; sparingly clothed with distinct pale yellow setie, those on the tibia more slender.

Head only slightly narrowed in front, finely but very definitely and closely granulate; clypeus uearly smooth. Thorux of equal length and breadth, the front angles attain the middle of the eyes; dise slightly transversely convex, with a linear impression along the middle, which, however, does not reach the base, its whole surface rather closely and distinctly granulate; it is widest before the middle, where the marginal channels are a little expanded, but nearly straight though a little narrowed towards the base; the margins are studded with granules, and appear therefore finely serrate; the base is oblique towards each side, so that the posterior angles are not sharply defined. Elytra incurved at base, with somewhat rounded crenulate shoulders which hardly exceed the thorax in breadth; they are a little marrowed posteriorly ; there is a broad shallow scutellar depression, bordered by a slight elevation of thie interstices;
they bear series of granules, which become confused at the extremity. Leys simple, of moderate length. Antennce sparingly and finely pubescent; basal articulation quite bidden from above, second stout and longer than third; eighth small and bead-like, ninth distinctly larger, tenth strongly transverse, eleventh rotundate.

Underside opaque, pitchy red, minutely setose; metasternum and basal ventral segment more distinctly granulate than the succeeding ones. The antemal furrows well narised.

A very distinct species, owing to the uniformity of colour and sculpture. One example has two indistinct impressions on the thorax near the base, and the shoulders are not evidently granulate or crenulate, but there is no other material difference.

Length $1 \frac{1}{2}$; breadth $\frac{1}{2}$ line.
Broken River. Another of Mr. Lewis's discoveries; three examples.

## Coxelus variegatus, sp. n.

Opaque, subohlong, subdepressed, medially narrowed, variegate; head and thorax fusco-rufous, the former the darker; elytra fuscous black, but with a broad oblique space from the scutellum to near the hind thigh, not inchading the dark shoulder, and another oblique interrupted band from near the suture to the side and top of posterior declivity on each clytron reddish, but paler than thorax ; antenne and tarsi red.

Head rather broad, granulate, rather thickly studded with coarse squamiform sete. Eyes prominent, coarsely facetted, setose. Thorax about one-third broader than long, closely and distinctly granulate ; the longitudinal furrow does not attain the base, near which two narrow oblique foveæ and an indistinct scutellar impression may be seen; the sides are only slightly rounded and gradually narrowed backwards; near the obtuse front angles the marginal channels are expanded ; there are no well-defined posterior angles; it bears numerous coarse yellow setre, which along the sides stand out beyond the margins. Elytra oblong, their sides and apices nearly vertical ; they bear series of granules, there are two broad median depressions and a narrow sutural one at the base; on the dark areas the setre are almost black, on the lighter parts they are yellow; at the su'ure on top of the declivity there are two small, narrow, black elevations or crests. Legs with moderately coarse setæ.

After a careful comparison with each of the described species, I find that no. 235) ( ( $\because$ oculator) most nearly resembles this species. In (. ocmlator, however, the head is much more narrowed anteriorly, so that it seems sultrigonal, its sculpture and setie are very much finer, the setie borne by the legs are finer, and the rounded black spots on the hinder part of the elytra are entirely different.

Length $1 \frac{1}{2}$; breadth $\frac{1}{2}$ line.
Iuvercargill. One from Mr. Alfred Philpott.

## Coxelus bicavus, sp. n.

Elongate, obscure ferruginous; elytra "ith some ill-defined dark spots: anteme and tarsi red; sparingly clad with moderately short, distinct, mostly erect and stout, greyish setr.

Head exramulate, each gramule with a minute puncture. Eyes rather smatl. Thoron of about equal length and breadth, withont distinet lateral margins, but serrate, a little rounded towards the not at all prominent auterior ansles, qradually narrowed backwards, posterior angles indistinct, base and apex a little rounded: its sculpture like that of the head, the granules evidently separated from each other, the median groove well maked in front, but not prolonged backwards much beyond the middle; at the base there are two elongated foves. Elytra oblong, rounded posteriorly, without obvious inequalities of surface, striate-punctate or granulate according to light during examination. Leys fincly setose.

A rather small species, which may be identified by the two elongate basal foree situated about halfway between the middle and sides of the thorax.

Length 12 ; breadth $\frac{3}{5}$ line.
Invercargill. Oue fowarded for examination by Mr. A. Philpott.

## Gathocles obliquicostatus, sp. n.

Suboblung, moderately convex, a little narrowed posteriorly; sparingly cluthed with fine, short, curled, yellow setre; ruto fuscous, a large area near the middle of elytra piceous; the front of the head, the antenuse, and legs red.

Head setose behind, with a few rery minute granules ; the basal suture of clypeus oblique towards each side, the apical truncate; labrum smooth. Thorax one-third broader than long, its sides rounded, but a little, almost simously, narrored near the base, chamelled, the margius thick, somewhat reflexed, and granulate ; the front at the middle is obtusely
prominent and has two short elevations, at the base two distinct oblique costæ enclose a triangular depression ; it is finely but distinctly granulate. Elytra quite as broad as thorax at the base, the sides and apex nearly vertical ; the suture slightly raised behind; on each elytron there is a distinct granular costa, which is curved outwards near the base and becomes nodiform on the summit of the posterior declivity, between it and the suture there are two series of granules or punctures when examined in different lights ; the external sculpture, though similar, is less definite.

Anterme 11-articulate; second joint obconical, stout, quite as long as exposed part of the basal one, third longer than fourth, joints $5-8$ head-like, ninth distinctly broader than eighth and about half the breadth of the strougly transrerse tenth, the terminal subrotundate.

This can be distinguished from Heterargus rudis: and the species of Guthocles by the distinct oblique elevations near the base of the thorax.

A variety occurs in which the sculpture is less definite. One antenua has only nine joints, the basal and terminal three are normal, as is the club; the missing intermediate ones are atrophied and coalesce so as to form one joint almost as thick as the second and about onc-thind as long as the whole length of the antenna.

Length $1 \frac{1}{2}$; breadth $\frac{5}{8}$ line.
Otara, Southland (Mr. A. Philpott).
Obs.-The genera Heterdigus and Gathocles, described almost simultancously at opposite sides of the earth, the former by Dr. Sharp, the latter by myself, are, I think, synonymous; but as Dr. Sharp did not state whether the antemix are 10- or 11-jointed, some uncertainty still exists.

## Protarphius tricavus, sp.n.

Body pale rufo-castaneous, obscured by sappy matter; antennæ and tarsi red.

Head with granular sculpture, the lateral prominences cover half of the basal joint of the antennæ. Thurax broader than long, the disk transversely convex and uneven, with two broad irregular ridges which are less elevated in front than near the middle; the intervening spaces assume the form of an elongate frontal and two foveiform basal impressions, near the sides there are a few minute granules; the lateral margins are thick, not much expanded and but little rounded, with obtise angles. Elytrol rather short, broader than thorax, transversely convex, the apex and sides vertical; on
each elytron, including the suture, there are three slight ridges, the external one is nodifurm on top of the declivity, they are apparently formed of gramules; there are two series of punctures between each two of these and an equal number nearer each side; when looked at in certain ways these serial punctures seem like granules; the lateral sculpture is illdefined.

Antenne with the basal joint oviform rather than cylindric and attached to the head by a slender stalk; joints $3-5$ obconical, longer than broad, third slightly longer than the others; 6-8 small and moniliform, ninth rather larger, transrerse; tenth abruptly enlarged, transverse; eleventh also large, rotundate. Antennal cavilies large, apparently not prolonged below along-ide the eyes. Eyes minute, with eoarse facets. Tibice fincly sctose, the anteror somewhat expanded externally near the middle, but a grod deal narrowed or almost notehed near the extremity. Mandibles bifid at apex. Mentum oblong, narrowed anterionly. Prostermm widely incursed in front, its flanks flattened but not in the least excavate. Coxce moderately separated. Metustermum of moderate length. Enipheara very narrow near the extremity. Abdomen in ith the basal segment nearly twice as long as the sceond, which is but little longer than the third or fourth, their sutures broad and deep.

The thorax is less rounded and prominent at the middle of the apex than in P. ruficornis.

Length $\frac{7}{8}$; breadth $\frac{1}{2}$ line.
Broken liver, Canterbury (Mr. J. H. Lewis).

## Protarphius posticalis, sp. n.

Body moderately transversely convex, covered with greyish scaly or sappy matter, and bearing fine, short, yellow setæ; it is fuscous, with pitchy-red legs and antennæ.

Head minutely gramulate. Thora.e rather large, about a third broader than long, with a frontal channel which, on the middle, becomes a large angular depression; two oviform depressions behind, a large one near each posterior angle, and an oblique transverse one towards each side in front, the intervals more or less obtusely elevated; its sides curvate, rather thick, and a little expanded; the sculpture indistinct, consisting apparently of shallow punctures. Elytra medially emarginate at base, slightly broader there than the base of thorax, a good deal curvedly narrowed behind ; at the base there are two moderate elcrations, the intervening space being hroadly depressed ; in line with these, near the middle,
there is a pair of less distinct nodosities; on top of the declivity there are four, the two nearest the suture being the largest ; their sides are vertical, but the posterior declivity is not as vertical as in other species, being a little prolonged; some slighter incqualities may be seen; the sculpture near the suture is serial, and may be termed either granular or punctiform according to different points of observation.

Tarsi finely setose. Anterior tibice seemingly slightly grooved along the front face. Antenne very sparingly pubescent, second joint obsonical and stout, longer than the uncovered portion of the first; third slender, evidently longer than the succceding ones; fourth and fifth longer than broad.

This species is most like $P$. indentatus as regards superficial inequalities, but the thorax is without indentations, the posterior slope is more gradual, and the insect itself is smaller. It is extremely difficult to determine the exact affinities of these species when one example only is available for examination.

Length $1 \frac{1}{8}$; breadth $\frac{1}{2}$ line.
Otara, Southland. One of Mr. A. Philpott's discoveries.

## Symphysius, gen. nov.

Antemue 11-articulated, club abruptly two-jointed. Tarsi very scantily piluse, almost bare underneath ; the basal three joints slightly longer below than above, the first joint rather longer than secoud.

The head behind the mentum is broad and plane, with sharply limited quite straight sides just outside, but inside of the eye there is a cavity, not a groove, wherein the basal joint of the antenna is accommodated.

In Ulonotus the oblique antennal furrow just passes, without encroaching on, the rounded imer margin of the eye, and passes uninterruptedly to the sculptured part of the head. The tarsi are thickly clothed and the claws thickened at the base.

In Recyntus the antemal groove is straight, but so expanded that the inner margin of the eye is shaved off and polished, so as to be quite truncate ; it is limited behind by a distinct oblique ridge, thus separating the smooth deep groove from the sculptured portion of the head.

## Symphysius serratus, sp. n.

Convex, suboblong; fuscous, the antenute and legs red; covered with greyish sappy matter and beariug fine setie.

Head with granular sculpture, dilated and elevated over the antemnal cavities. Thurux transverse, with broadly explanate sides; the anterior angles project to the front of the eyes; near the middle each side is so perforated as to indicate two lobes, the hinder one abbreviated, so as to be distant from the shoulder outside, but its imer termination forms a distiuct posterior angle; the disk has two elongate promiucnces projecting over the head, and two nodosities behind which are almost continuous with the frontal ones; the interval appears to be a broad channel. Elytria as wide as the thoras, their margins apparently scrrate, the sides and apex neariy rertical ; di-k rather flat but uneven, at the hase there are two curvate ridges extending backwards nearly to the middle, apparently with granules on their summits ; a little further back, on each elytron, near the side a straight granulated elevation is seen, and theee are two nolosities near the suture on the top of the declivity; on a small denuded space the suture is sharply defined, and there are two rather broad longitudinal lines which camnot be termed distinet flattened granules or punctures; the sides, near the margins, bear two series of granules; the shoulders project slightly, but there is an obrious gap between each of these and the thoracic lobes.

Tibice straight, externally serrate and finely setose. Anterme sparingly pubescent, basal joint stout, scarcely visible from above ; second also stout, longer than broall; third more slender, nearly as long as the fourth and fifth combined; joints ( $\mathrm{i}-8$ small aud moniliform ; ninth broader than the preceding one; tenth large and transerse, at least twice the width of the ninth ; elerenth also large and somewhat rounded.

Undersive fuscous, corered with sappy matter, the ventral segments gradually and slightly decrease in length, with straight deep sutures. Prosternum widely incurved in front, sultriancate in Ulonotus and Recyntus. Metasternum short, much more so than in Clonotus. Scutellum large.

Length 2; breadth 1 line.
Southland. Two from Mr. A. Plilpott; and one from Mr. J. H. Lewis, numbered 5237, so caked with dried sap and dirt that its sculpture cannot be discerned.

## Symplysius lobijer, sp. n.

Oblony, fuscous, covered with sappy matter, with bright yellow setæ ; tibiæ piceous, tarsi chestnut-red.

Head immersed up to the eyes, fincly graumlate, forehead
distinctly truncate in front; labrum shining, very prominent, strongly rounded and finely setose at apex ; mandibles red, minutely bifid at the extremity and with an imer central tooth. Thorax rather broader than long; from the apex for two-thirds of the whole length the side is formed of one thick, granule-studded curve bearing fine, short, curled yellow setæ, the basal space therefore, though straight, appears abruptly contracted and on a lower plane, the side, within the curved lobe, is broadly chamnelled; a pair of ridges start from the apex and are curved outwards at the middle; the surface is a little uneven, with granular sculpture. Elytra oblong, as wide as thorax, sides and apex nearly vertical, lateral margins indistinct and not perceptibly serrate ; disk nearly flat, studded with series of granules; third interstices smooth, a little elevated, nodiform and setose on top of the declivity, at the base there are two longitudinal, but not very elongate elevations, the humeral angles are obtusely rectangular. Tibice straight, fringed with short yellow setæ, but not serrate.

Antennee rather short and exhibiting malformation ; second joint stout, about as long and thick as the exposed portion of first; the third ionger than broad, longer than fourth; fifth distinctly longer than third ; joints 6-8 short ; in this case the fifth is probably made up of two joints. The other antemna has two distinct basal joints like those first described, then follows one long joint composed, I believe, of three coalesced articulations, the succeeding three are bead-like; ninth indistinct. Club stout, pubescent, biarticulate.

As there is only one specimen extant it is not easy to decide, by superficial examination alone, whether it is congeneric with the typical species. The antennæ, indeed, in perfect examples may be 10 -articulate, in which case this species would become the type of a new genus near Chorasus. It may be identified by the peculiarly curved, lobe-like sides of the thorax.

Length $1 \frac{5}{8}$; breadth $\frac{3}{4}$ line.
Invercargill (Mr. A. Philpott).

## Pycnomerus suteri, sp.n.

Elongate, subparallel, slightly nitid, mude, fulvescent; antenne and tarsi red.

Antennce with yellow pubescence, second joint longer than the exposed portion of the first, but, nevertheless, very short and transverse ; third slightly longer, narrowed at its base ; joints 4-9 transverse ; tenth nearly twice as broad as the preceding one: terminal joint rather longer aud narrower.

Head immersed up to the well-developed eyes, its punctuation close and distinct but not deep; the lateral plice thick near the antennse, curved and cariniform near the eyes, frontal impressions sma'l and subrotundate. Thorax about as long as broad, truncate in front, but with subacute projecting angles ; it is widest near the front, but very gradually and slightly narrowed backwards, posterior angles quite distinet and rectangular ; the lateral margins appear somewhat thickened in front, where the chamels ar : broader, towards the base they become thin and ar directed inwards so that they terminate at the ba-al margins inside, but quite fre from, the posterior angles ; its suiface distinctly but not closely puncture 1 , the long itndinal impres-ions distinct but not derp, the space between them nearly smooth. Scutellum transerse, smoth. Elytia broader than thoras at base, with somewhat prom nent shoulders, very gradually yet a good deal narrowed postrimily, evidently punctatestriate, the three sutural interstices, on each, appear elevated behind, with minute indistinct serial punctures; they are not at all explanate near the apices; the setee in the larger punctures are almost imperceptible.
$P$. impressus, from the same locality, is a more slender insect, its thorax has indistinct hind angles, the anterior angles are not prominent, and the apex is medialiy incurved. From all the wther species $P$. suteri is distinguished by its somewhat yellowish colour and details of form and sculpture.

Length $1 \frac{3}{4}$; breadth nearly $\frac{5}{8}$ linc.
The Hermitage, Mt. Cook. One individual, named after its discoverer, Mr. H. Suter.

## Pycnomerus ruficollis, sp. n.

Subparallel, elungate, nearly glabrous, moderately slining; head and thomax sanguincous, the antennæ, legs, and elytra pale ferruginous.

Anteme with a few outstanding greyish hairs: second joint as long and stout as the uucovered portion of the basal one; third distinctly longer than fourth, obconical ; 4-9 transverse : tenth abruptly broader ; eleventh narrower than tenth, roumded, densely and minutely pubescent.

Head (eyes included) rather narrower than front of thorax, with two deep frontal impressions, lateral elevations distinct, its punctuation fine and not clo-e. Eyes rotundate, moderately large aud prominent. Thorax slightly longer than broad, gradually narromed backwards, rery slightly
emarginate in front, anterior angles subacute and a little prominent ; ba*al margin broadly rounded, the angles, however, are almost rectangular ; its punctuation is distinct, hut not close except just near the lateral margins; there are two longitudinal impressions with an almost smooth central linear interval. Scutellum smooth. E'ytra slightly arcuate at the base and rather wider than the tho:ax, humeral aneles not dentiform ; their sides nearly parallel, being only slightly and gradually narrowed posteriorly ; they are deeply punc-tate-striate, but the punctures are not approximated, towards the extremity the punctures become obsolete though the strise are deeper; interstices with fine punctures, the second and fourth confluent at the extremity, the apical maresins somewhat thi: kened; the minute yellow pubsecence on the apical segment is quite discernible.

Cnderside nude, moderatcly shining, with distinct punctures, those on the stermm coarse but not close, abdominal punctuation less coarse, metasternum with a fine median groove behind.

In most respects similar to $P$. minor, the front angles of the thorax rather more prominent, the dorsal impressions well-marked and divided along the middle, and with the terminal two articulations of the antemuse definitely separated.

Length $1 \frac{1}{2}$; breadth $\frac{3}{8}$ line.
Broken River, Canterbury. A good series from Mr. J. II. Lewis, some a little larger and darker than the type.

## Group Mycetophagidæ.

## Triphyllus pubescens, sp. n.

Elongate, moderately convex, a little glossy; head and thorax and a large humeral space rufo-castaneous, elytra fuscous, legs and antennæ testaceo-rufous, club dull fuscous; covered with conspicuous yellowish pubescence.

Head fincly but distinctly and moderately closely punctured. Thorace subquadrate, but usually narrowed towards the depressed anterior angles, the lateral margins rather fine in front, with six or seven denticles near the base, the hindmost forming the posterior angles ; it is distinctly but not very closely punctate ; about m dway between the middle and each side there is a punctiform fovea. Scutellum quadrate, with a few minute punctures. Elytra of the same width as the thorax at the base, very slightly wider near the middle, shoulders a little elevated; their punctuation distinct near the basc, but not exactly seriate, and becoming
nearly obsolete behind the middle, there is a short linear impression near each side of the suture but no well-marked striæ.

Antenne glossy, basal two joints nearly equal, third rather longer than second; fourth obviously shorter than contiguous ones; joints $6-8$ become shorter and broader, the eighth being short and about half the width of the ninth; club opaque, evidently pubescent, large, triarticulate. Eyes transversely oval. Terminal joint of maxillary pulpi stout, truncate at apex. Torsi clongate, four-juinted, the basal joint longer than second.

Underside a little shining, ventral segments piceo-fuscous, fincly punctate, with slender greyish pubescenee; metasternum with a linear impression along the middle which becomes wider belind, its flanks closely and moderately coarsely punctured; prosternum distinctly punctured, rugosely at the sides.

In form and colour somewhat similar to $T$. serratus, 401 , which, however, has the fourth antemal joint relatively longer, the fifth rather thicker than and as long as the third, whilst six to eight are obconical and hardly at all transverse. One male only with trimerous tarsi seen in either species.
q. Length 1 ; breadth $\frac{3}{8}$ line.

Invercargill (Mr. A. Philpott); six specimens.

## Group Byrrhidæ.

## Pedilophorus pulcherrimus, sp. n.

Compact, convex, oval : brilliant viridi-ancons, the head, thorax, and base of elytra with metallic-red reflections, and bearing numerous minute, inconspicuous, grevish setre; femora piceous, tilix rufescent, tarsi testaceous, antennæ fusco-testaceous.

Head moderat ly coarsely punctured, more closely and finely near the eyes. Autennce sparsely pilose, basal joint thick, reddish; seeond cylindric, shorter and thinner than first; third slender, evidently longer than contignous ones ; 4-6 elongate, each rather shorter than its predecessor; 7 and 8 distinctly shorter and broader than preceding ones; 9 and 10 still broader, transverse; eleventh elongate. Thorax nearly thrice as broad as it is long, its sides finely margined, gradually narrowed towards the front, anterior and posterior angles almost acutely rectangular, apex widely incurved near each side, base obliquely truncate outwardly ; its punctuation nomhere ciose but as distinct as that of the
head. Scutellum small. triangular, not smooth. Elytiot widest near the middle, gradually narrowed behind, posterion declivity somewhat flattenel; their whole surface with minute irregular, linear impression so as to scem coriaccous; their punctuation distinct, a little finer than on the thorax, and more effaced near the sides, the extremity bears a few fine yellowish setæ.

Tibise slightly curved externally, with fine yellow pubescence, the anterior slightly grooved along the outer face ; third tarsal joint with an elongate membrane.

Underside sparingly clothed with fine yellow hairs, shining black, with iridescent reflections, closely and very distinctly punctured ; abdomen more finely and closely, fifth serment rather more distinctly but not as closely punctured as the others.

From Moryctus coruscans this may be distinguished by the coloration, \&e. In $P$. probus the anterior tibie are distinctly carvedly expanded externally between the middle and extremity, thus forming a broal receptacle for the tarsi. $P$. puncticeps has the outer edge of the tibise curved, but most dilated near the middle, so that the tarsal furrow is deep and extends from the knee to the apex.

Length 2 ; breadth $1 \frac{1}{8}$ line.
Invercargill. Two examples from Mr. A. Philpott.

## Group Melolonthidæ.

## Eusoma renealis, sp.n.

Subdepressod, elongate-oblong, somewhat glossy, glabrons, but with elongate lateral setæ, variegate ; fusco-testaceons, the clypeus, palpi, and basal four joints of antemas rufofuscons; thorax infuscate, each side of the middle, and the scutellum in the centre, fuscons; elytra with numerous irregular, more or less glossy eneo-fuscons spots, which become quite encous or violaceous towards the extremity.

Head short, convex, moderately, finely, and not at all closely punctured; elypeus narrowed anteriorly, with reflexed margins, apex truncate, the basal suture oblique towards each antenua, more closely and rugosely punctured than the vertex. Eyes large, moderately convex, rounded, above, finely facettel. Thorax twice as broad as long, its anterior angles projecting along the baval part of each eye, apical emargination subtruncate in the middle, base widely Lisinuate, wider than the front, with obtusely rectangular angles; the sides slightly curved, lateral and basal margins
fine but distinct throughout; the surface distinctly and irregularly but not coarsely or closely punctured. Scutellum large, minutely punctured, the dark spot almost smonth. Elytra elongate, oblong, somewhat expanded behind the middle, the apices, conjointly, broadly rounded, and finely margined nearly to the suture ; each has thee more or less definite costie, which, however, do not reach the apex, the suture is a little rufescent and elevated behind the middle and finely punctate ; their whole surface distinctly and irregularly punctured and uneven, the marg nal punctation is scrial. Leys pale brown, sparsely sctose, front tibie tridentate, tarsi long and slender.

U'uderside nearly nude, shiming fuscr-testaceous, the basal four ventral segments about equal, more or less longitulinally striate: metastermum irregularly punctate, medially channelled; prosternal process subtriangular, short, with a red median carina.

Anternce 8 -articulate, baval joint cylindrical at the base, knobbed at apex ; second short and thick; fourth quite as long as the elongate third, its basal angle di-tinctly projecting backwards but not elongated as in Sericuspilus advena; club with four equally elongate, strongly pubsecent leaflets.

Very similar to E. coste'la, with a shorter thoran, stouter legs, and differing in numerous details. The elytra more irregularly marked and decidedly more æneous and quite violaceous on some spots. Easily recognisable by the more slender and elongate fourth joint of the anteune. With the exception of the different structure of that $j$ int, Sericosjifus can hardly be separated from the older Eusoma.
$\delta$. Length $4 \frac{1}{2}-5$; breadth $1 \frac{3}{4}-2 \frac{1}{4}$ lines.
Westport. Two imperfect males from Mr. G. V. Hudson ; found by Commander J. J. Walker.

## Lewisiella, gen. nov.

Body subovate, moderately convex, almost nude, bearing only some minute ine mspicuous setre. Head broad. Labrum prominent, nearly horizontal, deeply emarginate. ('lypueus with reflexed margins, obtusely curvate. its basal suture nearly straight. Anteme 8 -articulate, ba*al joint elongate, rather slender, clavate towards extremity, only about half of its length exposed above, oblique and concare at apex; second slightly longer and much stouter than third; fourth short and stout, oblique at the extremity (sometimes thicker than the third and of the same length) ; fifth short, prolonged inwardly so as to be half or two-thirds the length of the
club, which is rather short, triarticulate, and fincly pubescent. Thora.e transverse, base widely bisinuate, apex widely emarginate, its sides rounded. Leys elongate; femora moderately dilated, grooved underneath: anterior tibise expanded, obtusely bidentate externally, the apex, however, prolonged so as to form a third tooth; the others asperate and spinose, the extremity of each with coarse spiniform cilia. Tarsi long, with simple claws. Anterior coce large and prominent, occupying almost the whole space from base to apex of the prosterum except the flanks; they are contiguous at the extremity, but there is an open triangular space in front. Metasternum short. Pyyidium scarcely visible above.

Nearly related to Odontria, but lacking the thick conspicuous clothing, and distinguished by the abbreviated metasternum and unexposed pygidium.

This being the third genus of the group discovered amongst the mountains of the South Island by Mr. J. H. Lewis, it is named in his honour.

## Lewisiella modesta, sp. n.

Subovate, a little nitid, fusco-piceous, legs pitchy red, antenne testaceous.

Head convex behind, strongly but irregularly punctured there so as to leave some smooth spots, the forehead closely, coarsely, and somewhat rugosely punctate ; clypens broadly rounded in front. Eyes almost hyaline. Thorase twice as broad as it is long, lateral margins distinct, the chanmels distinctly widened near the front, the sides evenly rounded, posterior angles nearly rectangular, but not acute; its surface convex, evidently punctured, interstices minutely sculptured; the anterior angles extend to the back of the eyes. Scutellum short, curvilinearly triangular, punctate. Ehytra convex, shoulders obtuse and of the same width as the thorax at the base, gradually dilated backwards, apices obliquely truncate towards the suture, the p.gidum visible from behind whon examined horizontally; each elytron has eight distinctly punctured strix, these, however, are sometimes shallow, interstices with distant punctures.

Cinderside shiming, piccous, scantily pilose, femora similarly clothed; epipleure quite linear except near the base; posterior coxal lamine projecting behind between the thighs beyond the base of the trochanters.

Length 6 ; breadth $3 \frac{1}{4}$ lines.
Manorburn, Otago. Found by Mr. J. H. Lewis.

## Lewisiella capito, sp. n.

Borly transversely convex, subbilong, unt pubescent, with some minute brassy setie only, subopaque, piceous black, antennse pitchy red, club opaque, densely minutely pubescent.

Head relatively larse, nearly as br ad as front of thorax, coarsely irrecularly punctate : elypeus prey obtuse, almost truncate in front, its frontal margin less elevated and reflexed than that of $L$. morlesta. Antenne short, second joint nearly as long as exposed portion of first, joints 3 and 4 about equal in length, the latter slightly stonter, each longer than broad, neither very elongate; fifth short, only slightly produced inwardly, not pubescent ; clinb triarticulate, rather short. Thora $e$ strongly transverse, its sides nearly straight, without distinct marginal channels, but flattened near the anterior angles, apes widely emarginate, base widely but not deeply bisinuate and resting on the elytra, posterion angles nearly rectangular but obtuse, the margins closely and distinctly punctured, no doubt, in perfect examples, fringed with coarse short sete; its surface with rather shallow, distinct, but not coarse punctures, all much fincr than those on the head, none very close to each other, there is an indistinct dorsal striz. Sicutellum smonth. Elytra ovate-shlong, very slightly rounded laterally, obliquely truncate at the extremity towards the suture, the pygidium, however, entirely concealed ; the suture is just perceptibly elewated posterionly; their strise rather shallow, their punctuation also not cearly defined; interstices distantly punctured.

The five rentral segments of nearly equal length, on a different level than the metastemum, so that they are not on the same plane as the epipleure, they are sparingly punctured and setose, basal segment almost longitudinally rugose. The metasternum short. Femora groned underneath.

Superficially very different from $L$. modesta, owing chiefly to the almost uncontracted front of the thorax and large head, but without well-marked structural cha acters that would warrant generic separation from Lewisie'la.

Length 6 ; beadth 3 lines.
Old Man Range, Otago, elevation 4000 feet. A single specimen from Mr. J. H. Lewis.

Odontria prelatella, sp. n .
Testaceous ; a transverse inter-ocular space, some irregular marks on the thoracic disk, the serial elytral punctures and
irregular marks occupying most of the fifth interstices and curved inwards towards the suture, besides other spots, fuscous.

Head almost uninterruptedly curved, the lateral margins being exactly continuous with the eyes, the space between the cyes with few but rather large punctures, the punctuation of the clypeus similar but closer and somewhat rugose. Thorax transverse, regularly and gently rounded at the sides, yet more narrowed in front than behind, anterior angles not acute, but covering the back part of the eyes, base bisinuate, posterior angles obtuse ; its sculpture, except the marginal setigerous punctures, quite indistinct ; clothed with fine decumbent oreyish hairs. Scutel'um pallid, rounded, nearly glabrous. Elytra of the same width as thorax at the base, widest near the hind thighs, considerably narrowed behind, apices truncate ; suture reddish ; their serial punctures fine, the clothing similar to that of the thorax, but not so thick. Pygidium much expos d, a little shining, very sparingly pilose, smooth on the middle, but with coarse sballow punctures elsewhere.

Antemne testaceous, second joint as stout as, but only half the length of, the basal one; third slender and elongate ; fourth nearly as long as thirl, with a spiniform process about one-third of the length of the club, which is clongate and quadri-articulate.

Underside testaceous, ouly sparingly pubescent.
ठT. Length $5 \frac{3}{4}$; breadth $3 \frac{1}{4}$ lines.
Invercargill (Mr. A. Philpott). One male of this well. differentiated species.

## Group Telephoridæ.

## Asilis pilicornis, sp. n.

Depressed, clongate, quite black, legs infuscate; head and thorax glossy, elytra less so.

Head fincly and indistinctly punctured at the sides. Thorax transverse, subtruncate and finely margined in front. base similarly marginate, truncate in front of the scutellum, but oblique towards the sides; lateral margins reflexed and broad, but becoming quite thin near the front ; close to the base a minute sinuosity causes the posterior angle to appear rectangular ; the punctuation is extremely fine, not at all close, and most easily seen near the sides; there is a transverse depression near each hind angle, and a lighter one before the scutellum. Elytra of the same width as the thorax at the baee, very slightly wider behind, their margins Ann. \& Mag. N. Hist. Ser. 8. Vol.iii.
indistinct near the shoulders ; their punctuation close, somewhat rugose, fine but distinct, and rather shallow; they are sparingly clothed with slender ash-coloured hairs, the sides, however, are more evidently pilose.

Antenne stout, clothed with short, rather thick pubescence; second joint evidently shorter than third, all longer than broad, eleventh slightly narrower than the preceding one; they reach backwards almost to the posterior femora.

Very much like $A$. leviguta, but with the antenne less serrate, and without the longitudinal central thoracic groove seen in that species, which, moreover, has less-defined sculpture on the elytra, so that these are more shining.

Length $1 \frac{3}{4}$; breadth 15 line.
Broken River (Mr. J. H. Lewis). One only.

## Asilis sinuellus, sp. n.

Depressed, moderately elongate, closely covered with fine ashy pubescence; head and thorax shining black, elytra rather dull ; legs infuscate, the knees and claws castaneous, antennæ quite opaque.

Thorax transverse, very finely punctured, nearly quite smooth on the middle, with a forea near each side at the base prolonged inwardly to the middle, this basal depression has a transererse series of small but distinct punctures, there is also a slight broad median depression near the base; lateral margins a little rounded, thickened or flattened at the middle only, a little narrowed but not sinuated behind, posterior angles almost acutely rectangular ; base medially emarginate, and widely slightly sinuated towards the sides. Elytra finely but distinctly and a little rugosely punctate. Antenne hardly attain the hind thighs.

On comparison with. A. tumida, 1195, it will be noticed at once that the thoracic punctuation of that species is quite close and distinct, that the ante-basal depression between the swelling on either side of it has a fine groove, that the basal margin is raised but not sinuate in front of the scutellum, and that there are three impressions on the head which are wanting in $A$. sinuellus, which, moreover, is smaller and less glossy.

Length $2 \frac{1}{2}$; breadth 1 line.
Otira Gorge. One individual from MIr. J. H. Lerwis.
Asilis granipennis, sp. n.
Subopaque, elongate, subdepressed, rather densely clothed with very sleuder cinereous pubescence; black, legs and
anteuna nigro-fuscous, joints $3-7$ of these latter greyish at the extremity, mandibles and claws infuscate red.

Antenne densely pubescent, reaching backwards to middle thighs; basal joint stout and distinctly longer than third, which is hardly longer than secoud ; 4-6 equal and rather thicker than the following ones; $7-10$ very slender at the base ; eleventh as long as tenth, elongate-oval. Head short, quite half the width of front of thorax, indistinctly and minutely sculptured. Thorax nearly twice as broad as long, very slightly rounded, with raised frontal margin, the anterior angles obsolete; its sides curved, with thick reflexed margins; base marginated, very slightly rounded, not medially emarginated, its angles indefinite ; the surface closely and minutely punctate and covered with very slender pubescence, depressed at the base. Scutellum broadly triangular, not smooth. Elytra as wide as thorax, their sides subparallel, distinctly margined except at the shoulders, apices individually rounded; their whole surface closely and rugosely but not coarsely punctured, and studded with minute granules on the intervals. T'arsi elongate, fourth joint of the posterior with elongate lobes, claws thickened and angulate.

Couderside dull black, closely and finely punctate and pubescent. Front and middle coxse contiguous. Metasternum with a slight mesial groore. Sixth ventral segment strongly incurved at the apex.

Larger and more opaque than $A$. simuellus, the elytra with less sharply definite punctures, but with granulate interstices, this last character being quite distinctive.

Length 3 ; breadth $1 \frac{1}{8}$ line.
Kaitoke. Four examples from Mr. G. V. Hudson.

## Asilis interstitialis, sp. n.

Elongate, muderately shiming, thatax glossy; black, legs and antenuse piceo-fuscous, claws and mandibles fuscorufous.

Head with two shallow inter-ocular punctures. Thora, widely bisinuate at the base, and with a slight angular excision in front of the scutellum, basal region depressed, with a punctiform fovea near each side, there is also a broad median impression behind, posterior angles subrectangular ; its surface with very fine, sharply defined, but not close punctures. Scutellum medially impressed. Ehytiol moderately coarsely and rugosely punctured.

Easily separated from $A$. yrumipennis by the coarser elytral
punctuation, with smooth shining intervals, and from $A$. sinuellus by the large size, \&c.

Length $3 \frac{1}{2}$; breadth $1 \frac{3}{8}$ line.
Kaitoke (Mr. G. V. Iudson). A single specimen.

## Asilis apicalis, sp. n.

Slender, parallel, depressed, moderately shining, with very fine greyish pubescence; black, legs and antennæ piceons.

Head rather dull, with minute rugovities. Thorux transversely quadrate, with obtuse but not broadly rounded angles, front and lateral margins of nearly equal thickness throughout, with a rather broad, ill-defined, abbreviated, discoidal groore, its punctuation not close and rather fine. Elytra very elongate, very gradually and slightly expanded backwards, rather finely and rugosely punctured, their apices strongly rounded singly so as to leave a sutural gap. Antenne relatively stout, joints 2-10 differing but little from each other.

Closely allied to $A$. piliventris, but distinguishable from it and the other species by the almost dehiscent elytral apices.

Length $1 \frac{3}{4}$; brearth $\frac{5}{8}$ line.
Karori, Wellington. Another of Mr. ('. V. Hulsou's discoveries.

## Group Melyridæ.

## Dasytes aurisetifer, sp, n.

Elongute, narrow, subopaque, black, covered with decumbent, rather short and slender, yellow setse.

Head wider than front of thorax, its frontal portion short and glabrous, antennal tubercles slightly elevated. Thorur as long as it is broad, the middle widest, constricted near the frout so as to be rather narrower there than at the base; its punctuation, like that of the head, rather indistinct. Scutellum black. Elytia evidently broader than thorax at the base, moderately incurred there, so that the obtuse shoulders seem prominent, apices rounded, sutural region depressed, somewhat closcly and finely punctured. Legs elongate : tarsi slender, the posterior newrly as long as the tibiæ; claws thickened, but with only minute pallid membranes.

Antennce clongate, bearing minute dark pubescence, first joint slender at the base, but strongly clarate at the extremity ; second stout, shorter than the basal one; third and fourth
of equal size ; 5-9 moderately serrate; tenth as long as the precerling, but less dilated at the apex; eleventh elongateoval and acuminate.

Fem. - Thorax shorter and relatively broader.
Length $2 \frac{1}{4}$; breadth $\frac{7}{8}$ line.
Central Otago. One pair of this handsome species from Mr. J. H. Lewis.

## Dasytes anacharis, sp. n.

Rather narrow, elongate, not dilated posteriorly, slightly nitid, sparingly clothed with fime suberect, greyish pubescence; crancous, antemnæ and tarsi picco-fuscous, legs piceous tinged with blue.

Head densely and minutely sculptured, with a few very small punctures and two broad interocular impressions ; it is, eyes included, rather wider than the front of the thorax. Antenure pubescent, joints 3 and 4 nearly twice as long as broad, the terminal rather slender. Thorax about as long as broad, much constricted in front, lateral margius distinct except in front, posterior angles rounded; its surface densely and minutely sculptured, and with some distant small punctures. Scutellum black. Elytra elongate, subparallel, only slightly expanded behind, somewhat broader than thorax at the base, shoulders moderately elevated; their punctuation close and fine yet distinct, the interstices indistinctly rugose. Tursi as long as the tibie; claws castancous, with distinct membranous appendages.

Cinderside shiming, blue, minutely punctate, with distinct pubescence. Mctasternum distinctly broadly medially grooved behind.

When compared with $D$. orcocharis, its nearest ally, its distinct elytral punctuation is at once apparent, the body is uniformly blne without any green tinge, and the head and thorax are rather broader. In D. oreobius the punctures are quite shallow.

Length $2 \frac{1}{2}-3 \frac{1}{4}$; breadth ${ }_{8}^{7}-1$ line.
My three specimens were given to me by Mr. E. W. Anderson, without any indication of locality.

## Group Cleridæ.

Phymatophoca lugubris, sp. n.
Elongate, narrow, slightly glossy, fuscous black; legs pale brown, base of femora and the knees fusco-testaceous.

Head (including the large and prominent eyes) rather
wider than the broadest part of the thorax, very coarsely and closely punctured so that the intervals are quite linear. Thoras nearly as long as it is broad, obtusely dilated laterally behind the middle, more abruptly narrowed behind than in front; its sculpture like that of the head, except that on the disk the interstices are perceptilly broader, the apex is infuscate and more fincly and distantly punctured, before the middle there are two small, smooth, slightly raised spots and two less distinct ones near the base; it is sparingly clothed with outstanding elongate grevish hairs. Scutellum opaque. Elytra hardly double the breadth of thorax at the base, their sides slightly and widely incurved; their punctuation coarser than that on the thoracic disk, but somewhat seriate near the suture; apex somewhat depressed and with the fine grey pubescence rather concentrated there.

Underside with fine pubescence, rentral segments shining blue, the breast more infuscate, coxe testaccous; metasternum consex, with fine transverse linear seulptare at the sides and base.

Antemue elongate, reaching to beyond the base of thorax, the basal eight joints are shining fuscous above, but the first two or three are testaceou underneath, and the long club is quite dark and opaque, lut in a reversed specimen testaceous below. P'alpi testaccous, the apical joints are, however, usually fuscous.

There is but oue species, $P$. atrata, at all like this, but it is only about half as large, it has no scutcllar depression, and the elytral punctuation is continued almost to the extremity of the apices, where there is no concentration of pubescence, their sides are very nearly straight and just apprecially and gradually narrowed towards the shoulders, and the thorax is proportionally longer.

Length $2 \frac{3}{4}-3$; breadth $\frac{7}{8}$ line.
l'aparoa, near Howick. Described from three examples in my own collection.

## Phymatophoea apicale, sp. n.

Elongate, slightly nitid, sparingly pilose, elytra more thickly; head and thorax piceo-fuscous, the front of the latter somewhat rufescent; elytra fuscous, apex fulvescent, the shoulders and two more or less distinct marks near the middle of each paler ; legs fuscous, knees paler, front tibiæ somewhat violaceous; antennæ and palpi pale brown.

Head very closely and distinctly punctured, the intervals
usually longitudinally rugose. Thorax evidently widest behind the middle, considerably obliquely narrowed behind, closely and distinctly punctured, with two slightly raised smooth spots before the middle, two others and a linear space near the base. Elytra slightly widened backwards, coarsely punctured nearly in longitudinal series, there is a sutural depression near the base bordered with slightly obtuse elevations, apex impunctate.
$V^{\prime} a r$.-Smooth spots on thorax and testaccous marks near elytral suture indistinct, antemnæ and legs paler.

Length $2 \frac{1}{2}$ lines.
$P$. opiloides is the nearest ally.
Length 3 ; breadth 1 line.
Waitakerei Range, Auckland. Described from specimens in my own collection.

## Metaxina, gen. nov.

Palpi short, robust; terminal articulation of the labial subtriangular or securiform, truucate at apex ; the maxillary longer, their last joint quite oblique at the extremity. Tarsi pentamerous; basal joint abbreviated above, its lobes prolonged below; joints 2-4 of nearly equal length, their lobes also prolonged but without perceptible lameltie underneath; fifth simple, nearly as long as the preceding four conjointly ; basal joints of the anterior furnished with long slender, brush-like setæ underneath. Eyes prominent, distiuctly facetted, apparently rotundate, in reality trausversely broadly oviform, not cmarginate. Prosternum truncate in front. Corce with trochanters; the anterior prominent, separated only by the thin prosternal process ; intermediate rather less prominent, almost contiguous; the posterior small, only moderately separated. Metasternum moderately elongate. Abdomen composed of six segments, the basal rather larger than the others, $2-5$ about equal; sisth short, deeply emarginate, with a supplementary conical segment protruding therefrom. Antemue 11-articulate, not clavate; inserted, not in cavities, but on slight prominences, or articulations, in front of the eyes; basal joint st ut, pyriform, third slightly longer than seco: dor fourth ; joints $4-8$ nearly equal, each longer than broad and narrowed at the base; 9 and 10 distinctly broader thau the preceding, but little longer; eleventh rather larger and oviform; these organs therefore more nearly resemble those of our l'oupris and Parmius than of Phymatophoea.

The type of this genus is quite unlike any Australian or

New Zealand species known to me, and is certainly an aberrant form, owing to the absence of tarsal lamellie, the unnotched eyes, \&c.

## Metaxina ornata, sp. n.

Subdepressed, elongate, shining; pubescence scanty, but near the sides consisting of long outstanding grevish hairs; varicgate, fuscous; the hasal two and the terminal joint of the antenne, the palpi, kners, tarsi, and a spot on cach side and base of thorax finco-testacerous, in one example the disk of the tharax only is fuscous, the other parts being of the lighter colour ; on eachelytron an irory-like lomule prosecds from the shoulders almost to the suture before the middle, it then exteuds backwards, and, in line with the posterior femur, bends obliquely behind it but does not guite attain the lateral margin.

Heud (eyes inclucled) nearly as large as thorax, forchead limited between the antenme by a slightly raised suture; its surface has lut few distinct amall punctures, the intervals, except on the middle, are den-ely and mimutcly sculptured. Thuiax somewhat corifiform, transerese, apes truncate, base rounded, the lateral margins are fine and curved towards the base, without forming posterior angles ; its senp pure sinilar to, but slightly coarser than, that of the head. Ecutellum clongate. Elytre prallel-sided, broader than thorax, with obtusely prominent shoulders; their punctuation moderately coarse, not close, and subseriate, apices not quite smooth.

Underside glossy pitchy-brown, pubescence scanty but elongate, flanks of metastemum distinctly punctured.

Length $1 \frac{3}{4}$; breadth $\frac{5}{8}$ line.
Broken River. Discovered by Mr. J. H. Lewis.

## Group Heleidæ.

## Cilibe lateralis, sp. n.

N"ude, opaque, fuscous black, antemæ and tarsi pitchyred ; orate-oblong, slightly transwersely convex.

Head slightly consex behind, finely and moderately closely punctured there, sliwhtly longitndinally rugose near the eres; forehead more finely and not so closely punctured on the middle, somewhat depressed towards each side where the punctuation is quite deuse. Thorax $5 \frac{1}{3} \mathrm{~mm}$. broad by 4 long at the sides, apex decply arcuate, anterior angles obtuse but extending to the front of the eyes, base widely bisimate; widest behind the middle, very slightly rounded
yet distinctly but gradually narrowed anteriorly, rather less narrowed behind, posterior angles distinct but not at all divergent, lateral margins distinct, the lateral slope is rather gradual, so that the channels are but little concave; its punctuation distinct throughout, not very coarse, very close and with narrow intervals towards the base, at the sides there are some minute granules. Scutellum broadly triangular, closely fincly rugosely punctate-granulate. Elytra only slightly wider than thorax at the hase, humeral augles almost rectangular but obtuse, their sides nearly straight as far as the hind thighs, but curvedly narrowed behind; the suture slightly elevated behind the middle; there are no obvious striæ, but there are some ill-defined broad interstices which can harilly be termed costic, two discoidal ones on each elytron are, however, most appareut ; the punctuation along the middle is rather close but not so coarse and intermingled with small granules; posteriorly the sculpture becomes more granular, and is similar though coarser towards the sides; the lateral margins are well developed and reflexed almost to the apex ; the marginal channels concave, widest from the shoukiers to near the hind thighs; there are no large punctiform impressions, the sculpture being granular but more transversely rugose behind.

Cuderside slightly shining, moderately closely and finely punctate, scantily and finely pubescent. Prosternal process with a deep groove at each side, its central portion rugose; front of prosternum evidently granulate, its flanks coarsely obliquely or longitudinally rugose, gramular near the coxæ, coarsely transversely rugose at the sides.

Leys simple ; tarsi with yellow pubescence; the antenne with similar fubescence from their fourth joint onwards; labrum with yellowish setæ.

The species most resembling this is, mudoubtedly, C'. gramulosa, which, however, may be recognised by the much coarser punctuation, rather longer thorax, flatter clytral suture, less reflexed elytral margins, and less concave chamels.

Length $5 \frac{1}{2}-6$; bieadth $3-3 \frac{1}{4}$ lines.
Ilammer. Three examples from Mr. J. H. Lewis.

## Cilibe smithiana, sp. n.

Body slightly transversely convex, oblong-oval, a little shining; head and thorax fusco-niger, elytra of a more chocolate hue, latcral margins somewhat rufescent; the labrum, palpi, antemur, and legs infuscate red.

Head closely and distinctly punctured, most closely and
rugosely between the eyes, with a distinct transverse depression close to the front of each eye; labrum fincly punctured, and bearing numerous conspicuous yellow sets ; epistome medially broadly convex. Thorax deeply emarginate in front, anterior angles blunt and extending beyond the middle of eyes, evidently and widely bisinuate at base, so that the subacute posterior angles appear to be directed backwards and to extend over the base of the elytra just within the humeral margins; it is slightly wider at the middle than elsewhere, but without the least angulation there; the sides behind are nearly straight, but more, though gradually, curvedly narrowed anteriorly, lateral margins equally thick and a little reflexed; there is a broad basal impression at each side of the middle; the surface is moderately finely and closely punctured, less closely on the middle. Scutellum simple. Elytra gradually and slightly dilated towards the middle, gradually narrowed posteriorly, marginal channels broad and concave, not so closely punctured as the disk, without large impressions, and not studded with granules ; disk moderately finely and closely punctured, interstices smooth, much narrower and more irregular near the sides, not granulate ; their coste ill-defined.

Legs shining, dark red above, tibiee with fine yellow pubescence, much more finely and not as closely sculptured as those of C. opacula, and densely ciliated at the extremity with short coarse fulvescent setr.

Underside shining, rufo-piceous, finely punctate, and minutely setose ; flanks of prosternum longitudinally rugose and rather distantly punctured, the raised middle portion finely and distantly punctured but distinctly granulate near the eyes, lateral margins slightly transversely rugose ; head irregularly punctate but not granulate; femora finely but not closely punctate and bearing rellow pubescence; anterior tibiæ closely and coarsely punctured, the others more finely. Epipleura nearly smooth before the middle, feebly transversely rugose behind.

When placed alongside my type of C. opacula it is seen that this species (C. smithiana) is obviously larger; the elytra are more narrowed towards the base and still more evidently towards the extremity ; the ill-defined costre are more distinct, the punctuation is rather deeper and coarser, there are no granules or marginal foveæ ; the hind angles of the thoras are more protuberant behind, and it is one-fifth longer in the middle. The eyes are larger. The tarsi (posterior) are a third longer. The antenuæ are more finely pubescent. The general surface less opaque.

Length 10 ; breadth 5 lines.
Manawatu Gorge. Named in honour of Mr. W. W. Smith, who has lately contributed to our knowledge of the insectfauna of that region.

## Group Helopidæ.

## Adelium hudsoni, sp. n.

Elongate-oliong, moderately convex, sparsely clothed with minute greyish seta; shining cupreo-fuscous, the sides more rufescent; legs castaneo-rufous, tarsi and antennæ ferruginous.

Head narrower than thorax, forehead evenly curred; rather finely and irregularly punctate. Thorux quadrate, almost as long as broad, its sides finely marginate and nearly parallel, being only gently rounded near the slightly prominent anterior angles, apex a little incurved, base subtruncate, posterior angles nearly rectangular and resting on the eiytra; its punctuation distinct, rather fine, somewhat irregular, nowhere close, rather finer at the sides, a basal inpression near cach side most closely punctured; there is a slight elongate lateral impression before the middle, and about a dozen forciform punctures are distributed over the disk. Scutellum broad, minutely punctate. Elytra elongate, rather wider than thorax at the base, very gradually narrowed backwards, but evidently more attenuate apically ; each elytrou with about twelve distinctly punctured striae, these are not always regular, sometimes the punctures are more conspicuous than the strix, yet even these are interrupted on certain spots, ali, however, are much deeper and confused towards the extremity ; the interstices bear series of minute punctures, they are only of moderate width and, on some parts, partake of the partial irregularity.

Underside glossy fuscous; the sides of prosternum, coxre, epipleura, and terminal ventral segment rufo-castaneous; abdomen rather finely reticulate-punctate; middle of the prosternum compressed, its fiauks finely irregularly strigose.

Near A. cheesemani and A. simplex. In the former the elytral striæ are more distinct and numerous, about twenty on each elytron, the thorax differing in form, being more deeply incurved at the base and apex and more rounded laterally. A. simplex I have not seen, but its description indicates a much less brightly coloured insect, with different sculpture.

Length $41-4 \frac{1}{4}$; breadth $1 \frac{1}{2}$ line.

Paradise Lake, Wakatipu.
Discovered by Mr. G. V. Hudson, whose name has been given to it.

## Group Melandryidæ.

Doxozilera, gen. nov.
Body elongate, almost parallel-siderl, very Euenemid-like. Head not deflexed and concealed. Eyes distinctly facetted, transerse, subreniform, their greatest bulh at the sides and below. $E_{i}$ issome with fine curvate suture. Labrum transverse and quite exposed. I'ulpi shont, the latial erpecially; the maxillary not serrate, terminal joint subenltriform. Antennce inserted in cavitics just in front of the eres, reaching backwards nearly to the apex of metasternum in the male, shorter in the female, filiform ; hasal joint moderately stout, second about half the length of the third ; joints 3-10 elongate-oboonical, terminal slightly longer than tenth. Thurax much narrowed anteriorly, with distinct basal fover, posterior angles rectangular but host acute. Elytiol of nearly same width as thoras at the base, very slightly attenuate posteriorly. Anterior coace contiguois, the prostemal process not extending between them, with trochanters; the intermediate not prominent, the narrow mesosternal process interposed. Netusternum transversely convex, clongate, with a central groove behind the middle. Abdromen composed of five nearly equal segments. Leys rather short. Tibice slender, the apical calcar of the anterior stout, those of the others small and slender. Tarsi clongate and slender, penultimate joint of the anterior not truly bilobed but excavate above, basal joint longest ; in the posterior pair the first joint is nearly double the length of the other three combined. Claus divergent, distinctly dentate near the base.

The small typical species is vers different from our NewZealand Orchesia allies from no. $\tilde{7} 10$ to $\% 1 \%$ inclusive ; Ctenoplectron bears but little resemblance, whilst no. 708 more nearly resembles the Australian Talayra. From all the other genera of the true Melaudryidæ this is distinguished by the distinct tooth near the base of each claw.

## Doxozilora punctata, sp. n.

Body slightly nitid, black, clothed with fine ash-coloured pubescence ; antennæ and tarsi fuscous.

Head immersed up to the eyes, nearly vertical in front, its punctuation moderately fine and close but rather shallow.

Thorax relatively small, rather broader than long, without distinct lateral margins above, the base widely but fecbly bisinuate; when examined sideways the sides are seen to form a curve from base to apex, the most prominent and deflexed portion being near the middle; when looked at from above the apex appears nearly half the breadth of the base; there is an oblicque constriction or impression at each side in front, and a large well-marked fovea near each side at the base, posterior angles not projecting, the whole surface moderately closely and finely but distinctly punctate. Scutellum indistinct, obscured by minute greyish pubescence. Elytra slightly but broadly longitudinally depressed behind, the suture simple but well developed, their surface closely, distinctly, and rugosely punctured.

Underside nigro-fuscous, with decumbent greyish pubescence, rather finely punctured, metasternum most distinctly.

If the thoracic posterior angles projected backwards this insect might be easily mistaken for a sinall black Eucnemid or Elater.

Length 2; breadth $\frac{5}{8}$ line.
Broken River.
We are indelsted to Mr. J. H. Lewis for bringing this interesting little beetle to light.

## Group Edemeridæ.

## Selenopalpus rectipes, sp. n.

Subopuque, cyaneous ; the palpi, anteuna, and legs nigrofuscous; pubescence inconspicuous, cinereous.

Head immersed up to the eyes, narrowed anteriorly, with a broad groove along the middle of the clypens; interantennal impressions shallow, vertex slightly longitudinally elevated, finely and closely punctured in front, more distinetly but not so clasely behind. Thorax widest before the middle, sinuated behind; the basal margin, however, not contracted, and a little prominent at the sides; the surface finely and closely punctate, with a small antescuteliar impression. Scutellum small, medially grooved. Elytro wider than thorax at the base, slightly and very gradually expanded behind, their sculpture rather fine and close, yet ill-rlefined, not evidently punctiform nor granular, slightly rugose, the suture distinct, the two discoidal lines on each also ill-defined.

Legs rather slender, tibire very nearly straight.
The clavate posterior femora and thick, curvate, apically prolonged tibire distinguish S. cyanen. In S. aciphylle the
head is very oviform, the eyes rather distant from the thorax, flat, and strongly transverse, the basal margin of the thorax is more distinct and more protuberant at the sides, the hind tibiæ are stout and curvate, and the notch of the maxillary palpi is wide but not deep; in S. rectipes the apical emargination of the palpi is more like that of the typical species, S. cyanea, but the insect itself is smaller.

तै. Length $3 \frac{1}{2}$; breadth $1 \frac{1}{8}$ line.
Otira Gorge. One; found by Mr. J. H. Lewis.

## Baculipalpus maritimus, sp. 11 .

Elongate, subdepressed, slightly nitid, testaceous; tips of mandibles and the tibial spurs piccous; elytra sometimes with a pale fuscous vitta along each side; clothed with fine, slender, decumbent hairs similar in colour to the derm.

Head not constricted behind, vertes convex, depressed auteriorly, and finely setose there, with an angular infuscate space behind each eye; its surface not very closely punctured, interstices minutely sculptured; epistome and labrum truncate in front, both a little depressed in the middle. Thorax subcylindric, moderately narrowed behind the middle, base and apex slightly incurved ; its surface a little uneven, its sculpture like that of the head, rather shallow. Scutellum curvilinearly triangular, not smooth. Elytra elongate and subparallel, rather wider than thorax at the base, apices rather sharply rounded individually, so that the apical rentral segment is risible between then-it does not, however, protrude; inside each shoulder an indistinctly elevated line proceeds backwards, the sculpture is shallow, rather coarser than that of the thorax, and a little rugose. Legs long and slender.

Tibice finely bicalcarate. Front tarsi rather narrow, basal joint elongate and cylindrical; second and third triangular ; penultimate rather short, hardly at all expanded, excavate above but not truly lobate ; fifth slender, claws thickened and angulate at base; basal joint of the posterior longer than the remaining three combined. Eyes large, transverse, not rotundate, almost trunca'e in front and behind, distinctly facetted, extending dornwards, and not prominent as in Thelyphassa and Dammarobius. Mandibles bifid at apex. Maxillary palpi elongate, basal joint short, second elongate, third short, oblique at extremity; the terminal attached to the preceding one by a short stalk near its hinder part, so that the long frontal portion estends forwards three or four times as much as the other part is prolonged backwards; the
outer edge is widely incurved throughout its whole length, the imner is straight for two-thirds of its length, but forms a curve towards the extremity, the width barely exceeds a fourth of the length. Antenne filiform, extending backwards to the hind thighs, inserted on the front just before the eyes ; basal articulation slightly bent, gradually thickened, rather longer than third; second nearly twice as long as broad.

Male.-Abdomen finely sculptured and pubescent; penultimate ventral segment with a semicircular line in the middle which, in some lights, might be mistaken as indicating an excision, the extremity with a series of small setigerous triangular projections; terminal segment deeply medially cleft.

Female.-Terminal ventral segment simple, much narrowed towards the extremity. Last joint of the maxillary palpi subtriangular, its apex oblique. Niddle of head and thorax more or less infuscate longitudinally. Apices of elytra sharply rounded.

Differs from the corresponding sex of $B$. rarus by the absence of the longitudinal sulcus on the vertex, by its longer thorax not being narrowed near the anterior angles, and by the elytra being more dehiscent at the extremity.

む. Length $4 \frac{3}{4}$; breadth $1 \frac{1}{8}$ line.
Invercargill.
This interesting species was found under logs on the seabeach by Mr. A. Philpott, about forty years after my unique specimen of $B$. rarus was found on the Waitakerei Range.
Mount Albert, Auckland, N.Z., 26th June, 1908.

## LIV.-Twelve new European Mammals. By Gerrit S. Miller.

'The collection of European mammals in the British Museum contains representatives of ten hitherto unnamed forms. These are here described, together with two new races of Sorex included among some material sent to me for examination in London by the authorities of the United States National Museum.

Sorex araneus fretalis, subsp. n.
Type.-Adult female (skin and skull). B.11. no. 8. 9. 2. 1. Collected at Trinity, Jersey, Channel Islands, July 14, 1908,
by R. II. Bunting, Esig. Original number 3. Presented by Oldfield Thomas.

Characters.-Like forer aranous araneus, but skull with rostral portion shortened, broakmed, and deepened, and anterior teeth $\left(i^{i}, i^{2}, i^{3}\right.$, and $\left.i_{1}\right)$ more robust than in the mainland animal. Colour essentially as in true aromeus, except that the unlerparts in several of the Jersey specimens are a pale, almost whitish huffy gry, decidedly lighter than in any skins of the other races yet examined.

Measurements.-l'ype. ILeal anl body 63 mm . ; tail $48 \cdot 2$; lind font 13; condylo-lasal length of skull 15.5 ; mandible 10.0 ; upper tooth-row 8.4 .

Specimens examined.-Five, all from the island of Jersoy.
Sorex araneus bergensis, subsp. n.
Tiype.-Adult female (skin aml skull). No. $8166 \pm$ U.S. National Museum. Collected at (iravin, Harlanger, Norway, June 10, 1898 , by Thora Stejneger. Oryinal number 13.

Inignosis.-Larger than Sires aranens aranens (hind foot $13 \cdot 6$ to 14.4 mm . ; condylo-hasal length of skull 19 to 20 mm .) and colour in summer prlase darker, the dark hown or hackish domsal area sharyly defined from yellowish brown of sides.

Mrasurements.-Type. II eal amd body 50.5 mm. ; tail $44 \cdot 5$; hind foot $1: 3 \cdot 6$; condylo-hasal length of skull $1 . n \cdot \frac{1}{\text {; man- }}$ dible $10 \cdot 2$; unfer tonth-mw $s .6$. Averare and extremes of eleven specimens from the lhergen dhetriet, Norway: head and body $75 \cdot 7$ ( $76-53$ ) ; tail $4 \cdot 3 \cdot 3(44-56)$; hind foot $13 \cdot 8$ ( $13 \cdot 6-14 \cdot 4$ ).
sperimens carminer.-Twenty-six, from the following. Incalities in South-western Norway:-Skjerdal, Nordijord, 7; Opheim, Bergen, 4; Grarin, Bergen, S (U.S. N. M.) ; near city of Bergen, 7 (B. M. and U.S. N. M.).

Remarks.- 'This large race of Sorer araners differs notice--ably from the small true archeus of Siweden and Eastern Noiway, and more nearly resmbles the Pyrenean and Alpine races. Fiom these large forms, however, it is distinguishable by its darker colour. Its range appears to be confined to the Athantic slope of Western Norway. Un the eastern watershed it is replaced by true araneus, even as far north and west as the upper portion of the Gudbrandsdol.

Sorex araneus pyrenaicus, subsp. n.
Type.-Adult female'skin an 1 skull). B.M. no. S. S. 4. 301.

Collected at l'Hospitalet, Ariège, France (altitule 4700 ft .), August 25, 1903, by G. S. Miller. Original number 7076.

Characters.-Very similar to Sorex araneus tetrajonurus, but distinguishable by the duller, less evidently tricoloured summer pelage (winter coat not known), in which the back rarely if ever assumes the blackish tints often seen in thu Alpine form *.

Measurements.-Type. Head and body 72 mm . ; tail 51 ; hind foot 14 ; condylo-basallength of skull 20.0 ; man lible 10.0 ; upper tooth-row 88. Averare and extremes of six specimens. from the type locality: head and body $70 \cdot 6$ (69-72) ; tail 47 ( $44 \cdot 4-51$ ); hind foot $13 \cdot 3(13-14)$.

Sypecimens examined.-Thirty-two, from tho following localities in the Pyrenees :-Porté Pyrénéss-Orientales (Spanish watershed), 9 ; l'Hospitalet, Avièe, 12 ; Ax-le:Thermes, Arièze, 2 ; Barères, Hautes-Pyrénées, 9.

Sorex minutus lucanius, subsp. n.
Type-Adult (skin and skull). B.J. no. 8. 9. 1. 5. Collected at Monte Sirino, Lagonegro, Italy, by A. Robert. Original number 2585.

Diagnosis.-Similar to Sorex minutus minutus, but with molars and anterior upper incisor noticeably enlarged.

Measurements.-Head and body -; tail $42 \mathrm{~mm} . ;$ hind foot 104 ; condylo-basal length of skull 16 ; mandible 8.0 ; upper tooth-row $7^{\circ} 0$.

Specimen examined.-The type.
Sorex alpinus hercynicus, subsp. n.
Type.-Adult male (skin and skull). No. 112923 U.S. National Museum. Collected at Mäuseklippe, Bodethal, Harz Mountains, Germany, October 18, 1901, by F. I.. J. Bottcher. Original number 265.

Diagnosis.-Similar to Sorex alpinus alpinus, but with smaller skull and teeth (condylo-basal length of skull 19 to $19 \cdot 6$ instead of $19 \cdot 4$ to 20.6 mm . ; upper tooth-row $8 \cdot 6$ to 9 mm .).

Measurements.-Тype. Head and body 71 mm .; tail 67 ; hind foot $15 \cdot 4$; condylo-basal length of skull 192 ; mandible 10.0 ; upper tooth-row 8.1 .

Specimens exdmined.-Eleven (all in the U.S. National

[^58]Museum) from the following localities in Germany:-Balrenberg, Harz MIs., 2 ; Mäuseklippe, Bode Valley, Harz Mts., 2 ; Eulengrund, Silesia, 3 ; Wolfishau, Silesia, 2 (the last two localities in the Riesengebirge).

Remarks. - In external measurements the Alpine sheew of the Harz Mts. and Riesengebirge agrees with the swiss animal ; but the differences in length of skull and of torthrows seem enough to warant the recognition of the two forms as distinct.

## Crocidura canex, sp. n.

Type.-Adult male (in alcohol). B.M. no. St. '). 14. 2. Crete (no exact locality).

Diagnosis.-Size and general appearance as in the smaller. forms of Crocidura russula, and skull with similaty deep cranium ; but second upper premolar as large as third, and entire anterior portion of "pper tooth-row unusually long relatively to cheek-teeth.

Measurements.-'Type. Head and body 6.5 mm. ; tail 42 ; hind foot 11.8 ; condylo. Dasal length of skull $10 \cdot 4$; upper tooth-row 8.2.

Syecimens examined.-Two, both from the island of Crete.
Sciurus vulgaris segura, subsp. n.
Type. Adult female (skin and skull). B.11. nn. S.9.24.3. Collected at Molinicos, Sierra de Segura, Jaen, Spain, October 2, 1907, by M. de la Escalera.

Characters.-Similar to Sciurus vulgaris infuscatus (Cab)rera) of Central Spain, but back less hlackish, its underfur light grey, tail less red and with white area on under surface less well developed (essentially absent in three among eleven skins), and cheeks light grey, not noticeably contrasted with white of throat.

Colour.-Summer pelage : upperparts a fine inconspicuous grizzle of wood-brown and blackish, the general effect resembling the mars-brown of Ridgway, blackening on flanks, across postenior half of back, and on postern-extemal side of thighs (in some specimens the light element is more nearly russet and the black is essentially absent) ; ears and crown like back, but face with a rusty wash, and muzzle and cheeks to behind base of ears light clear ecru-drab, so pale as to form no marked contrast with white of throat; underfur of head, back, sides, and limbs pale ecru-lrab like that of cheeks, appearing consplicuonsly at surface in specimens with abmaded pelage; feet a dull fernginous, this colour extenting up
outer side of thigh and over entire fore leg, in both regions diluted by the ecru-drab of underfur; entire underparts and inner surface of legs buffy white to base of hairs; tail blackish, slightly tinged with dull red, the hairs becoming ecru-drab at base; whole tail sprinkled with pure white hairs, more numerous along median line below than elsewhere, and usually forming a distinct white median area as in S. v. infuscatus.

Skull and teeth.-The skull and teeth do not differ appreciably from those of the Central Spanish form.

Measurements.-Type. Head and body 245 mm. ; tail 195 ; hind foot 61 ; condylo-basal length of skull $51 \cdot 8$; zygomatic breadth 33.4 ; mandible 35.6 ; maxillary tooth-row (alveoli) 10.4 ; mandibular tooth-row (alveoli) $10 \cdot 0$.

## Evotomys glareolus istericus, subsp. n.

## 1930. Evotomys hercynicus hercynicus, Miller, Proc. Wabhington Ient.

 Sci. ii. p. 100, July 2(; 190) (not Hypuleus hereymicus, Mehlis, 1831).Type.-Adult male (skin and skull). B.M. no. 4. t. 6. 72. Collected at Bustenari, Roumania, May 3, 1899, by IV. Dodson. Original number 88.

Characters.-Audital bullæ more abruptly inflated on inner side than in the typical subspecies ( $=$ Evotomys hereynicus rubidus, Miller, 1900) ; colour lighter and brighter (dorsal area rather narrow, clear yellowish rufous or a little more brownish, slightly varied by dark hair-tips ; sides a noticuably contrasted buffy grey, produce! by a grizzling of cream-buif mixed with blackish and whitish hairs; underparts varying from creamy white to a yellowish cream-buff; feet buffy white; tail distinctly bicolor, dark brown above, buffy white below).

Measurements.-T'ype. Head and body 96 mm. ; tail 43 ; ; hind foot $17 \cdot 4$; condylo-basal length of skull $23 \cdot 2$; zygomatic breadth 13.0 ; mandible $14 \cdot 2$; maxillary tooth-row (alveoli) $5 \cdot 0$; mandibular tooth-row (alveoli) $5 \cdot 0$.

Specimens examined. - Forty-one, from the following localities:-Bustenari, Roumania, 1; Hatszeg, Itunyad, Austria-Hungary, 11; Somorja, Western Hangary, 1; Marxheim, Bavaria, Germany, 28.

Remarks.-Contrary to my supposition in 1900, the redbacked vole of the Harz Mountans, together with that of Denmark, proves to be the dark form named rubidus by Baillon. This being the case, the suppused diserepancies in
the original description of Mus glareolus, Schreber *, disappear $\dagger$, and the name Evotomys glareolus becomes available for the small European red-backed voles, and in a subspecific sense for the dark western continental form. The Ecolomys hercynicus of my preliminary revision is thus !eft munamet. Its range appears to be about coincident with the drainage system of the Danube.

## Microtus sarnius, sp. n.

Type-Adult male (skin and skull). B.MI. no. 8.9.2.27. Cullected at St. Martin's, Guernsey, Channel Islands, July 23, 1908, by R. H. Bunting. Original number 52. Presented by Oldfield Thomas.

Characters.-Like the large forms of Mirrolus agrestis (condylo-basal length of skull about 25 mm .), but middle upper molar with second inner triangle absent; colour above essentially as in M. agrestis agrestis, though somewhat less dark and reddish; underparts a strongly contrasted light grey (nearly the grey no. 9 of Ridgway).

Measurements.-Type. Head and body 118 mm . ; tail 42 ; hind foot 18.5 ; condylo-basal length of skull 27.8 ; 2y fomatic breadth 16.0 ; mandible 17.4 ; maxillary tooth-row (alveoli) 6.8 ; mandibular tooth-row (alver, i) $6 \cdot 5$.

Specimens examined.-Eight, all from the island of Guernsey.

Remarles. - While its external and cranial characters show that this species is a member of the Nicrotus agrestis group, the pattern of its enamel folding is exactly similar to that of M. arvalis. In the suppression of the second inner triangle of $m^{2}$ it shows the extreme of a tendency the exact opposite to that which has produced the local Hebridean form, i1. agrestis exsul. The eight specimens, though representing all ages from less than half-grown young to fully adult, show no noteworthy variation in colour or in teeth.

## Pitymys provincialis, sp. n.

Type.-Adult female (skin and skull). B.M. no. 8.8.4.265. Collected at St. Gilles, Gard, France, April 26, 1908, by G. S. Miller. Original number 7605 .

Characters.-A small member of the Pitymys ibericus group (hind foot about 14.6 mm . ; condylo-basal length of

[^59]skull 22.6 to 23 mm . ; upper tooth•row about 5 mm .) ; skull essentially as in $P$. duodecimcostatus, except for its much smaller size ; audital bullee very small and flat; colour pale (type: upperparts a light wood-brown, becoming paler and more cream-buff on sides; underparts a light grey, formed by the blending of slate-grey under-colour with creamy white of hair-tips; feet soiled whitish; tail whitish throughout, the upper surface sprinkled with brown hairs).

Measurements.-Type. Head and body 96 mm . ; tail 22 ; hind foot 14.6 ; condylo-basal length of skull 22.4 ; zygomatic breadth 14.4 ; mandible $15 \cdot 3$; maxillary tooth-row (alveoli) 5.3 ; mandibular tooth-row (alveoli) 6.2 .

Specimens examined.-Five from the type locality ; two skulls from Var, France (no exact locality) ; a skull labelled "Provence" and another marked "France."

Remarks.-From its nearest geographical ally, Pitymys duodecimcostutus, this species is at once distinguishable by its much smaller size, a character in which it resembles the small Iberian forms related to $P$. lusitanicus. From these latter it differs, however, in the conspicuously projecting upper incisors and very narrow interorbital region.

## Mus spicilegus hispanicus, subsp. n .

Type.-Adult female (skin and skull). B.M. no. 8.8.4.101. Collected at Silos, Burgos, Spain, October 12, 1906, by G. S. Miller. Original number 7272.

Characters.-Like the Hungarian Ifus spicilegus spicilegus, but general colour paler and more yellowish (back and sides ranging from buff to a pale buffy grey, lighter and less yellow than the cream-buff of Ridgway, the median dorsal region faintly "lined" with black, the sides gradually becoming clear buff or buffy grey, this colour continuing forward over cheeks and above eye to muzzle; basal portion of hairs slate-grey ; underparts sharply defined buffy white, slightly clouded by slate-grey under-colour; feet and tail like belly, the tail with a narrow dusky dorsal area extending to tip; ears thimly clothed, their colour buffy or greyish in harmony with surrounding parts).

Measurements.-Type. Head and body 79 mm . ; tail 50 ; hind foot $14 \cdot 4$; condylc-basal length of skull $19 \cdot 4$; zygom matic breadth 11.0 ; mandible 11.4 ; maxillary tooth-row (alveoli) $3 \cdot 4$; mandibular tooth-row (alveoli) $3 \cdot 2$.

Specimens ex mined.-Seventy-one, from the following localities in Sprain:-Silos, Burgos, 12; Castrillo de la Reina, Burgos, 3 ; Venta del Baul, Granada, 7 ; Elche, Ali-
cante, 24 ; Alcoy, Alicante, 12: San Cristobal, Minorea, 7 ; Inca, Majorca, 6.

Tiemarks.-The yellowi-h form of Wus spicilernus characteristic of the central and southern portions of Spain is readily distinguishable from the clear greyish-brown animal of IIungary. Skins from the Balearic Islands, while not so yellow as those from the mainland, appear to be referable to the same race.

Mus spicilegus lusitanicus, subsp: n.
Type.-Arlult male (skin and skull). B.M. no. 98. 2. 2.30. Collected at Cintra, Portugal, Jamiary 25,1596 , by Oldfield Thomas. Original number 52 . Presented by the collector.

Churacters.-Essentially as in Mus spicilegus spicilogus and I. s. hispanicus, but colour of upperparts a light yellowish wood-brown with an evident russet tinge, the sides paler and more bufiy ; a narrow clear buff area on sides bordering the jale cream-huff of unterparts and accentuating the line of demareation.

Mrasurements.-T'Tpe. Inead and body it mm. ; tail 60 ; hind font 16.2 ; condylo-bazal leneth of skull $19 \cdot 5$; zygomatic breadth 10.6 ; mandible 11.6 ; masillary touth-iow (alveoli) $3 \cdot 6$; mandibular tooth-row (alveoli) 30 .

Specimens cireminct.- Six, all from the neighbourhood of Cintra.

LT.-Descriptions of new African Lepidoptera. By G. T. Bethune-Baker, F.L.S., F.'Z.S.

## Lycænidæ.

Oberonia trypherota, sp. n.
§. Both wings white, with blackish markings. Primaries with apex and termen broadly blackish, apes extending for two-thirds towards the end of the cell, termen shortly inraded upwards very finely with white from the tornus: secondaries with a postmedian curved row of fine grey dashes, closely followed by the subterminal grey scalloped line, the scallops extending iuto the narrow black termen, and so enclosing a serıes of terminal black spots with white irides; a dusky patch at the apex; fringes whitish. Underside: primaries with a curved postmedian row of fine, grey, isolated, inter-
nervular dashes, followed by a very fine, slightly scalloped, grey line, closely succeeded by a terminal row of blackish spots; termen finely black: secondaries with two basal black spots, one in the cell, one above it, a black spot at the apex, and a smaller one about halfway along the inner margin; an irregular series of isolated grey dashes, broken inwards below vein 3 ; the upperside terminal markings showing through very finely.

Expanse 32 mm .
Hab. Makala, Congo Free State, July.
In my collection and that of Major Porrell-Cotton.

## Notodontidæ.

## Elapirodes, gen. nov.

§. Palpi upturned, barely reaching vertex, roughly and thickly scaled; antenmæ fasciculate; legs roughly haired. Ncuration: primaries, vein 2 at a quarter before the lower angle, 3 just before, 4 from the angle, 5 from just above the middle of the discocellulars; $6,7,8,9,10$ stalked, 8 and 9 on a very long stalk just in front of the apex, 9 and 10 about midway between end of cell and apex, 11 from twothirds along the cell ; 12 long, terminating ouly a little before 11 : secondaries with 3 and 4 stalked from the lower angle, 5 from the middle of the discocellulars, 6 and 7 stalked from the upper angle (the stalks in both cases are short), 8 appressed on to the cell for a third.

Type, Elaphrodes nephocrossa, B.-B.
This is near Phalera, but the neuration is not quite similar and there is no areole.

## Elaphrodes nephocrossa, sp. n.

む. Primaries ochreous grey, with the base broadly dark grey; a broad wedge-shaped band in the median area of the ground-colour, its broadest side being on the costa ; a broad dark band from the apex to the inner margin up to the tornus, hollowed slightly in the middle externally, with its internal edge very deeply serrated ; reniform dark: secondaries pale straw-colour, with termen very broadly dusky, indefinite as to its internal edge.

Expanse 56 mm .
Hab. Ituri Forest, between Makala and Beni.
In the Powell-Cotton collection.

Gargetta concolora, sp. n.
$\delta$. Both wings uniform dark brown. Primaries rather darker than secondaries, with the least trace of a dark dotted median line and a trace of an angled postmedian line, also a trace of a paler scalloped subterminal line: secondaries markless.

Expanse 40 mm .
Mab. Makala, Congo Free State, May.
In the Powell-Cotton collection.
Metopolophota, gen. nov.
Palpi thickly scaled, end segment minute, barely reaching the apex; antemae bipectinate to the tips ; face roughly scaled, with a projecting tuft below the socket of each antenna; thorax probably tufted (but the single specimen is rubbed). Primary with extreme base of costa curved, then straight to near ajex, when it is suddenly depressed ; termen rounded at apex, receding and slightly hollowed; wing narrow, expanding but slightly: secondaries subtriangular, with arched costa. Neuration : primaries with vein 3 from just before the apex, 4 from the apex, 5 from just above the middle of the discocellulars; $6,7,8,9,10$ stalked, 8 and 9 on a very long stalk just in front of the aper, 9 terminating on the custa; 11 long, from two-thirds along the cell : secondaries with 3 and 4 from the lower angle, 5 from the middle, 6 and 7 on a short stalk from the upper angle.

Type, Metopolophota epinephela, B.-B.

## Metopolophota epinephela, sp. n.

ठ. Head and thorax whitish grey. Primaries creamy grey, with a broad dark brown costal dash extending into the cell towards the middle; inner margin scaled with brownish; a broad dark streak below the cell from vein 2 to vein 4 ; termen broadly brownish except at apex ; a trace of a costal spot beyond the cell and two small ones below each other in front of the apex; fringe tessellated white and brown : secondaries uniform spotless dull brown.

Expanse 34 mm.
Hab. Ituri Forest, between Beni and Makala.
In the Powell-Cotton collection.

## Arbelidæ.

## Marshalliana nubifera, sp. n.

§. Primaries grey, dusted more or less all over with darker grey, densely and darkly in a broad line below the cell, with an L-shaped extremity ; a very broarl and dark postmedian area from the costa to below vein 2, extending inwards below the cell into the angle of vein 2 ; costa darkly dusted, as also the termen, but the latter is interrupted by paler veins; a dark elongate lozenge patch in the cell : secondaries uniform brownish grey.

Expanse 32 mm .
Hab. Nairobi, April.
Type in my collection.

## Metarbela endomela, sp. n.

ठ. Frons pale grey, vertex dark brown, autennæ pale brownish grey, collar pale brownish, thorax and dorsal tufts dark brown, abdomen pale greyish brown with darker dorsum. Primaries pale greyish brown, reticulated more or less distinctly all orer with dark lines; the only lines at all prominent are an oblique one from the costa at a quarter from the apex and a short oblique one from the centre of vein 2 to the imer margin at a third from the tornus; these and all the other reticulatory lines are fine; a short, broad, dark basal dash below rein 1: secondaries pale grey, finely reticulated. The reticulations in both wings are very irregular.

Expanse 34 mm .
Hab. Kamililo, Nandi Country, January.
Type in my collection.

## Metarbela obliqualinea, sp. n.

§. Head and thorax ochreous grey ; abdomen dirty pale grey. Pimaries pinkish ochreous, with a dark greyish line along the lower part of the cell to beyond vein 2 , from where it descends obliquely to the tornus, the oblique part being eflged internally with creamy white; the usual Arbelid dotted lines are more or less present, less in the postmedian area and condensed into the basal area, so that it has a very pinkish shade: secondaries pale creamy white.

Expanse 30 mm .

Hal. British East Africa, Nairobi, February ; Machakos, Kedong, Mutito-wa-N'du ; Uganda, Hoima.

Type in my collection from Nairobi. Specimens in the British Museum from the other localities.

## Limacodidæ.

## Miresa melanosticta, sp. n.

$\delta$. Head and antennæ ochreous brown; thorax and abdomen madder-brown. Primaries madder brownish grey, with a basal, dark purplish-brown, somewhat wedge-shaped patch below the cell, edged externally by a waved, very oblique, ochreous line from the costa at a quarter from the aper to the inner margin at about a third from the base; a shorter, ochreous, rather open $V$-shaped mark from about vein 5 to the iuncr margin near the tornus, in the upper stroke of the $V$ are two lolack dots; an oblique ochreous subapical dash from the costa, edged iaternally by a dark purplish line and externally by a small indetinite similar patch; termen finely ochreous grey ; fringes madder-brown: secondaries uniform madder-brown.

Expanse 36 mm .
Hab. Kamililo, Nandi Country, June.
Type in my collection.

## Parasa charopa, sp. n.

§. Head and thorax orange farn-colour ; patagia edged laterally with green; abdomen cream-colour. Primaries bright orange-red, with a broad pale green band from the lower margin of the cell to the middle of the imer margin, externally bordered by a fine black line; veins in postmedian and subterminal area finely blackish: secondaries ochreous creamy. Both wings are very thiuly scaled, giving a subhyaline appearance.

Expanse 27 mm .
Hab. Mawamba, Makala, Congo Free State, March 1906.
In my collection and that of Major Powell-Cotton.

## Narosa nephochloëropis, sp. n.

ठ. Head, thorax, and abdomen whitish; fore legs pale green, ringed with white, Both wings white: primaries more or less clouded with green in the basal area and extending slightly into the median area; a broad postmedian cloudy band of green, angled strongly outwards between veins 5 and 7, and bordered broadly with grey; termen
finely green, edged internally with a narrow white line; fringes white and green interspersed: secondaries shiny white, with white fringes.

Expanse 25 mm .
Hab. Elburgon Railway Station (Uganda Railway), July 2, 1903.
ln my collection.

## Narosa hedychroa, sp. n.

ठ. Head, thorax, and abdomen white, middle segments of the latter brownish grey. Primaries whitish, slightly scaled more or less all over with pale smoky brown, which colour dcepens in the postmedian area into a dark spot, from whence descends a strongly serrated brown line to the inner margin; termen with fine internervular dark dashes: secondaries suffused all over with pate smoke-brown.

Expanse 20 mm .
Hab. Makala, Congo Free State.
In my collection.

## Narosa trilinea, sp. n.

o. Head and thorax yellowish white, abdomen dirty white. Primaries white, with three orange-yellowish sufffused indefinite bands, sharply edged externally with white, viz. a broad band below the cell, an irregular median one angled outwards on the fold, a postmedian one interrupted at vein 3 , and a short subterminal clond from the costa confluent with the latter; a dark terminal spot just above the tornus: secondaries uniform creamy white.

Expanse 16 mm .
Hab. Makala, Congo Free State, April 1906.
In my collection.

## Paraphanta rufilinea, sp. n.

J. Ifead, thoras, and abdomen red-brown. Primaries reddish brown, with a darker reddish basal area extending to about the end of the cell and obliquely terminated, edged externally with a fine white line; subterminal line reddish from before the apes, obliquely straight to the imer margin in front of the tornus; termen finely reddish: secondaries uniform pale straw-colour.

Expanse 18 mm .
Hab. Entebbe, Uganda; Makala, Congo Free State.
In my collection and that of Major Powell-Cotton.

## Lasiocampidæ.

## Leipaxais ituria, sp. n.

d. Thorax pale ochreous, abdomen pale rufous brown. Primaries pale ochreous grey, with an irregular rufous antemedian line, followed by a spot in the cell; postmedian rufous line oblique, serrate, and irregular, followed by a rufous tinge over the pale ground-colour ; subterminal line highly irregular and serrated, almost fractured at vein 3, from where it descends obliquely to the inner margin; termen clonded with very pale rutous: secondaries uniform warm rufous, with a very fine dark terminal line.

Expanse 46 mm .
Hab. Marramba, Makala, March 1906.
In my collection and that of Major Powell-Cotton.

## Lymantridæ.

## Olapa makala, sp. n.

才. Thorax dirty grey, abdomen yellowish grey, all the legs whitish. Both wings hyaline milky white: primaries with a trace of a grey dash closing the cell : secondaries with a small distinct black spot near middle of the inner margin, but on the basal side of the middle.

Expanse 43 mm .
Hab. Makala, Congo Free State, July.
In my collection and that of Major Powell-Cotton.

## Euproctis mediosquamosa, sp. n.

ठ . Head cream-colour, thorax and abdomen pale strawcolour. Both wings creamy white: primaries with base suffused with bright palish straw-colour; a curved strawcolour median line, a similar postmedian line, the interspace being sparingly suffused with dark scales except on the costa, where it is broadly bright straw-colour; a trace of another similar line and a similar interrupted subterminal line somewhat obscure: secondaries uniform whitish.

Expanse 29 mm .
Hab. Makala, Beni, July.
In the Powell-Cotton collection.

## Lalia beni, sp. n.

む. Head, thorax, and abdomen slightly yellowish; antennæ greyish. Both wings milky white, somewhat diapha-
nous, secondaries more so than the primaries: primaries with two small black spots, a round one in the angle of vein 2 and a longer one closing the cell : secondaries spotless.

Expanse 37 mm .
Hab. Makala, Beni, Ituri Forest, July 1906.
In the Powell-Cotton collection.

## Lelia kitchingi, sp. n.

d. Head and collar orange-yellow, thorax creamy, abdomen ochreous. Both wings pure white, with a black spot closing the cell : primaries with a small spot of black scales on the costa near the base, with an obscure and very slight dark costal irroration for about half the length of the cell.
.Expanse 48 mm .
Hab. Patigo, Acholi Country, 4000 feet.
In my collection.

## Hypsidæ.

## Solve disticta, sp. n.

${ }^{3}$. Head orange-yellow ; antenne yellow, with dark grey pectinations; collar and mesothorax deep orange, with a black lateral spot ; metathorax pale smoke-grey; abdomen pale smoke grey, with the dorsum yellowish on the penultimate segments; ventral surface yellowish. Both wings uniform very pale smoke-grey, with a single black spot at the end of the cell in each wing; the secondaries are rather paler than the primaries.

Expanse 38 mm .
Hab. Entebbe, Uganda, December.
Type in my collection.

## Arctiidæ.

Estigmene ochreomarginata, sp. n.
ठ. Head and thorax dark brown ; abdomen yellow, with black dorsal spots. Primaries uniform spotless dark brown, with costa narrowly ochreous: secondaries uniform pale straw-colour.

Expanse 36 mm .
Hab. Patigo, Acholi Country, 4000 feet, and Ituri Forest, Congo Free State.

In my collection and that of Major Powell-Cotton.

## Noctuidæ.

## Borolia confluens, sp. n.

o. Head and thorax very pale whitish grey, abdomen cream-colour. Primaries pale ochrcous grey, with a very pale slightly brownish stripe along the fold almost confluent with a similar stripe from the termen along vein 4 ; a similar coloured wedge-shaped dash above the tornus; a similar coloured indefinite dash from the costa at the aper to the reniform stigma; orbicular stigma very pale and small, pupilled with pale brown, confluent with the equally pale reniform, which is also centred with pale brownish: secondaries uniform whitish.

Expanse 30 mm .
Hab. Nairobi, April.
Type in my collection.

## Westermannia ochreoplaga, sp. n.

ס. IIead rufous brown, thorax and abdomen dull brown. Primaries dull brownish, with a trace of a wared basal paler line; a broad, oblique, ochreons-grey, median band, curved on its internal edge, excurved rather strongly below the costa on its external edge and then waved; an almost parallel subterminal pale brown line, darkly spotted and dashed on its external edge, with a paler margin to the spots and dashes; termen finely dark: secondaries uniform darkish brown.

Expanse 20 mm .
Hab. Makala, Congo Free State.
In my collection, also in that of Major Powell-Cotton.

## Hypothripa sexilinea, sp. 1 .

§. Head and thorax pale grey, collar with a dark bar, abdomen brownish. Primaries clear pale grey, with a curved, sharply defined, black basal line from the costa into the base; a twin, deeply curred (almost angled) on the fold, fine dark median line, the inner of the two being fainter and finer than the outer of the twin lines; a postmedian similarly curved pair of lines, but the curve is in the radial area and the outer line of the two is the fainter; these two lines arise in a large dark grey costal patch; subterminal line sharply defined blackish, waved and slightly serrate; a short curved dark line from the tornus to the postmedian line; termen fincly black, with fine black points betreen
the veins ; a dark short indefinite dash below the apex in the terminal area; fringes pale grey, with two dark dividinglines: secondaries darker grey.

Expanse 23 mm .
Hab. Makala, Congo Free State, April 1906.
In my collection and that of Major Powell-Cotton.

## Arcyothora mesonephele, sp. n.

f. Frons ochreous grey ; vertex and collar pale greyish, the latter tipped with white; thordx greyish, with ochreous patagia. Primaries pale brownish grey, with a restricted ochreous basal patch, extending but little below the cell ; a dark strongly ex-angled postmedian line edging the brownishgrey area, in the angle of which (line) is a good-sized patch of whitish-grey irroration ; area beyoud this line ochreous, with a terminal brownish patch between reins 2 and 6 ; two small brownish costal spots in front of the apex : secondaries brownish grey, with pale costa.

Expanse 24 mm .
Hab. Makala, Congo Frce State, March.
In the Powell-Cotton collection.

## Ogovia angulata, sp. n.

ठ. Head and thorax pinkish grey, abdomen darker grey. Both wings pale ochrcous grey: primaries more or less irrorated with pale piukish red; a curved antemedian pale reddish line rising in a dull reddish costal spot; reniform reddish, a largish costal pale reddish patch before the apex ; costa more or less reddish grey, with a few spots on it ; a trace of a subterminal row of grey internervular dashes; termen with a row of dark points between the veins, termen finely dark: secondaries with the termen broadly grey.

Expanse 52 mm .
Hab. Ituri Forest, Mawramba to Makala, March 1906.
In the Porrell-Cotton collection.

## Ercheia excavata, sp. n.

of Head, thorax, and abdomen darkish grey. Primaries darkish grey, with a basal blackish line, sharply waved ; an outwardly oblique, strongly marked, interrupted, dark median line ; postmedian line subcrenulate and somewhat obscure ; subterminal double line subserrate, excavated outwardly in the radial area, followed by another serrate line; termen with a preterminal strongly crenulate dark line; reniform stigma
obscurely dark; above the tornal area is a clourly whitishgrey indefinite patch: secondaries uniform dull brownish grey, with darker, indelinite, waved median, postmedian, and subterminal lines.

Expanse 59 mm .
Hab. N'tebi, Uganda, August.
Type in my collection.
Ophiusa pectinicornis, sp. n.
ठ. Head and thorax pale brownish; abdomen pale ochreous grey, with darkish grey dorsum. Primaries pale brownish, with a chestnut tinge in parts ; a double dark spot at the base on the costa; a broad, dark, strongly waved antemedian line, with a pale internal edge ; orbicular stigma traceable, with a dark point in it ; reniform chestnut-colour, with a dark edging; postmedian line double, dark, with paler infilling, very strongly and acutely angled near the costa, angle filled with pale ochreous ; a chentnut patch on the costa above the angle : a small grey apical patch divided from the chestnut one by a curved whitish line; a curved, oblique, subterminal row of dark spots; all the wing more or less darkly irrorated: secondaries dark grey, paler towards and at the base.

Expanse 50 mm .
Hab. Ituri Forest, Congo Free State.
In the Powell-Cotton collection.
Capnodes pyrochroa, sp. n.
§. Palpi red ; head and collar ochreous, irrorated with red; thorax reddish ochreous; abdomen grey. Primaries red, with the basal half mixed with ochreous; a subbasal indefinite line of grey, followed by a dark dot in the cell, which is edged externally by a larger spot of ochrcous; reniform grey, postmedian line dark grey, serrate, excurved below the costa, below which it is waved basewards; area beyond this line mostly grey with red showing through; subterminal line serrate and indefinite: secondaries red, with a subbasal, oblique, dark grey line and faint traces of postmedian and subterminal lines ; costa, apex, and termen somewhat clouded with grey.

Expanse 36 mm .
Hab. Ituri Forest, Congo Free State.
In my collection and that of Major Powell-Cotton.

## Diomea disticta, sp. n.

ठ. Head, thorax, and abdomen dark brown. Primaries dark umber-brown, with darker indefinite autemedian and median bands; beyond the latter the postmedian area is slightly irrorated with greyish, in which are two small, distinct, cream-coloured spots, one beyond the ceil, the other on vein 2; a trace of a very interrupted dark band following these; subterminal line dark velvety, strongly waved three or four times, in which is a small dark patch above the centre; termen with internervular cream dots, edged iuternally with small dark velvety dentations: sccondaries like the primaries, with most of the markings more or less distinctly carried through, but without the two creamcoloured spots.

Expanse 30 mm .
Hab. Ituri Forest, Congo Free State.
In the Powell-Cotton collection.

## Deltoidinef.

Sarmatia indenta, sp. n.
of. Head, thorax, and abdomen greyish. Primaries with the base pale greyish brown up to the dark deutate antemedian line; median area rather darker up to the broadish indented white postmedian line, area beyond this whitish grey finely irrorated with whitish, the central portion of it being tinged with deep cream and margined externally by an angled line of the same colour ; a darkish, cloudy, apical costal patch and a less dark, smaller, cloudy, curved, indefinite dash around the tornus; termen darkly dotted: secondaries uniform brownish grey.

Expanse 32 mm .
Hab. Makala, May.
In the Powell-Cotton collection.

## Hypena leucosticta, sp. n.

ठ. Head and thorax dull chocolate-brown, abdomen greyish brown. Primaries dull pale chocolate brown, with a fine antemedian line broken inwards at the upper margin of the cell and very oblique outwards from the lower margin of the cell ; a darkish dot at the end of the cell; pale postmedian line twice indented outwards and waved, a dark patch from thence to the apex edged internally by a short, curved, costal white dash; two velvety, deep brown, irregular small

[^60]spots at the bottom of the dark patch ; tiro subapical small white spots below each other; termen very finely dark, edged internally by a fine whitish line: secondaries uniform brown.

Expanse 32 mm .
Hab. Ituri Forest, Congo Free State.
Type in my collection.

## Hypena poliopera, sp. n.

〕. Head and thorax pale madder-brown ; thorax maddergrey, with dark dorsal tufts on the two penultimate segments. Primaries pale purplish brown, with an obscure angled and waved paler auteniedian line, darkly edged externally ; postmedian line oblique, composed of a series of crescents gradually increasing in size, edged interually with rufous, more broadly at the imer margin ; two cloudy, dark, obscure, somewhat parallel lines, subterminal line composed of a row of white spots, darkly edged internally, somewhat waved ; termen finely dark, edged internally by small lanceolate fawn-coloured internervular dashes; a pale lavender-grey costal patch borders the postmedian line and extends into a large similar apical patch, and on the inner margin near the tornus are two similar spots: sccondaries uniform greyish brown.

Expanse 42 mm .
Hab. Ituri Forest, Cungo Free State.
In my collection aud that of Major Powell-Cotton.

## Hypena orthogramma, sp. n.

ठ. Head, thorax, and abdomen dull olive-brown. Primaries uniform dull olive-brown, with a slightly oblique and slightly incurved white postmedian line; an obscure trace of a waved row of subterminal dark dots, edged in some cases internally with whitish: secondaries uniform dull brown.

Expanse 32 mm .
Hab. Makala, Congo Free State.
In the Powell-Cotton collection.

## Agaristidæ.

Eigocera tricolora, sp. n.
Palpi porrect, second segment with a broad fringe of long black hairs below, ringed beyond with a creamy fine line, end segment dark brown; head and thorax black; abdomen,
dorsum narrowly black, laterally and ventrally chromeyellow. Primaries black, inner margin broadly bright crimson-red for over three-quarters, base black, with a cream dot at the roots; a very oblique broadish cream baud across the antemedian and median areas, interrupted in the former area by the black ground ; a small subcostal creamy spot in the middle of the costa; a large, subovate, oblique, postmedian, creamy patch; a metallic leaden-blue line edges the main markings : secondaries bright crimson-red, with termen broadly deep black, very slightly tapering, narrower near the anal angle.

Expanse 48 mm .
Hab. Makala, April and June.
In my collection and that of Major Powell-Cotton.

## Rhanidophora septipunctata, sp. n.

〕. Head and thorax yellow ; palpi black, with restricted yellow bases; abdomen rose-pink. Both wings dore-grey : primaries darker than secondaries, with three white cellspots, that in the middle and the one at the end of the cell being large; a white spot above, the last of the three, a small white spot between the first and second but below the cell, a white spot on the inner margin at a quarter from the base, and another just beyond the middle, all the spots more or less round: secondaries with a pale pink suffusion at the base, in the cell, and along the inner margin.

Expanse 59 mm .
Hab. Makala-Beni, July.
In the Powell-Cotton collection.

## Geometridæ.

## Negla iturina, sp. n.

of ㅇ. Head and thorax whitish, spotted with black ; abdomen yellowish, with a row of black spots on cach side of the dorsum. Both wings white, spotted with blackish: primaries with a subbasal row of three spots, the largest being that on the costa; beyond this are two larger costal spots; a postmedian waved row of six or seven spots; a large apical black area, terminating abruptly below vein 4, below this the terminal blackish area is continued, the white ground deeply invading it at the veins; cell closed with an oval spot: secondaries with a spot closing the cell; a postmedian curved row of seven roundish spots ; termen broadly blackish in deep scallops, caused by the white ground invading deeply
the black, in some cases extending fincly through to the fringes.

Expanse 49-51 mm.
Hab. Makala and Ituri Forest, March-July 1906.
Tu my collection and that of Xajor Powell-Cotton.

## Pyralidæ. <br> Pyralinze.

Stemmatophora flammans, sp. n.
Ifead and thorax red. Primaries flame-red, with ochreons irroration in parts ; a double-angled median line from the eell to the inner margin, in the inner angles of which are small patches of ochreous; postmedian line strongly crenulate and waved, edged externally with ochreous; sulbterminal and inner marginal areas sonewhat ochreons, as also the internervular spaces of veins 2 to 4 : secondaries very pale straw-colour ; the whole of the wings have a slightly lustrous appearance.

Expanse 38 mm .
Hab. Makala, Congo Free State, May.
In the Powell-Cotton collection.

## Pyrautstine.

Pilocrocis mubilinea, sp. n.
§. Head and thorax pale chrome-yellow, abdomen darker. Both wings pale chrome-ycllow, with greyish markings: primaries with a small basal costal spot, followed by a second costal spot; a small subbasal patch below the cell; a median V-shaped mark ou the inner margin, with a small dot above the imner stroke of the $V$ and a large one above the outer stroke; a subterminal irregular broad line strongly angled outwards about vein 6 ; a short broad dash from the aper to near the angle of the previous line, and almost touching it at the lower extremity : scondarics with a small dot in the cell, a short dash below the angle of vein 2, a strongly thricewaved postmedian line ; an apical dash to about rein 5.

Expanse 28 mm .
Hab. Ituri Forest, Congo Free State.
In the Powell-Cotton collection.

## Phryganodes flavipectus, sp. n.

d. Palpi ochreous yellow, terminal segment dark grey : head, thorax, and abdomen dark sooty brown; legs creamy ochreous yellow, hind pair with dense dark tufts. Both
wings uniform dark sooty brown : primaries markless except for a trace of a dark spot at the end of the cell : secondaries with a single small ochreous dash, almost a spot, at the end of the cell.

Expanse 34 mm .
Hab. Makala, Congo Free State, April.
In the Powell-Cotton collection.
Phyganodes stygichroa, sp. n.
ס . Head and thorax dark greyish brown, abdomen slightly paler. Both wings darkish greyi-h brown : primaries with an antemedian dark line from the upper margin of the cell to the inner margin ; postmedian line very irregular, strongly projected outwards between veins 2 and $\check{5}$, where the edge is crenulate, receding rapidly basewards along vein 1 and descending to the margin in a short double curve; this line is somewhat edged externally with creamy, and has three deep cream-coloured dots below the costa: secondaries with the postmedian line only, similar to that in the primaries, but without the three cream-coloured dots.

Expanse 37 mm .
Hab. Makala, Congo Free State, May.
In my collection and that of Major Powell-Cotton.

## Sylepta fulviceps, sp. n.

of. Head and collar tawny, thorax and abdomen pale grey. Both wings uniform pale slate-grey, with a hustrous bluish-lilac sheen in certain lights: primarics with a very fine small subbasal pencil of dark purplish scales just below vein 1 .

Expanse 38 mm .
Hab. Makala, Congo Free State, April.
In my collection and that of Major Powell-Cotton.

## Glyphodes incomposita, sp. n.

§. Head, thorax, and both wings dove-grey, the latter with pearly diaphanous patches finely and darkly edged. Primaries with a median patch across the cell from the costa, fullowed by a small costal spot; a broad postmedian patch to vein 2 , deeply indented by the end of the cell : secondaries with a broad median patch projected outwards at its centre and extending slightiy towards the anal angle.

Expanse 30 mm .
Hab. Makala, Congo Free State ; Lagos.
In my collection and that of Maior Powell-Cotton; alon (from Lagos) in the British Muscum.
LVI.-Description of a new Ilesperid from Feru, belonging to the Subfamily Pyrrhopygine. By Hamilton H. Druce, F.L.S. \&c.

## Yanguna mabillei, sp. n.

б. Upperside: fore wing blue-black, with a pure white transverse central fascia commencing broadly just below the subcostal nervure and extending to the submedian nervure, where it becomes narrowed to a point and divided by the black nervules, i.e. the median and the lower median nervule; base of wing broadly and unevenly bright red; cilia reddish brown. Hind wing: basal and discal areas bright red ; inner margin, apex, outer and abdominal margins broadly and evenly blue-black; extreme basal areas thickly clothed with deep black hairs; cilia from apex to anal angle, where it is longest, reddish brown.

Underside: fore wing blue-black, with the white transverse fascia as above and a slight reddish irroration at the base. Hind wing blue-black, with a distinct, clearly defined, bright red fascia commencing on the costal margin close to the base and extending to the middle of the wing; cilia of both wings as above.

Head black, with tro whitish spots between the eyes; collar grey; thorax bright red interspersed with black hairs. Abdomen black, annulated with bluish grey ; anal tuft reddish brown. Palpi black, with sone grey scales. Legs black, finged with grey. Antenna black.

$$
\text { Expanse } 24 \text { inches. }
$$

IIab. Huancabamba, E. Peru, 6000-10,000 feet (Buettger, type Mus. Druce).

This fine insect, although somewhat like Y. cometes, Cr., has not the white fringes of that group, and seems to be allied to the species lately described and well figured by MM. Mabille and Boullet in 'Amales des Sciences N゙aturelles,' 9 th series, Zool. t. vii. p. 186, pl. xiii. fig. 2 (1908; It differs from that, however, by the broad white transverse hand on the fore wing and by the more exteusive red on the hind wing below. Described from two specimens, one of which has the cilia of the hind wings more concolorous with the border, and which may be its more usual colouring.

LVIT.-Diagnoses of new Mammals collected by Mr. II. C. Robinson in the Malay Peninsula and lhio Avchipelago. By Oldfield Thomas and R. C. Wroughton.
(Published by permission of the Trustees of the British Museum.)
The National Museum owes to the authorities of the S'langor Museum, and especially to Mr. H. C. Robinson, a further magnificent collection of mammals of all groups, and of these a full account is being forwarded to the 'Journal of the Federated States Museums.' In the meantine, however, to avoid clashing, it is thought better that the following: diagnoses should be published at once.
(1) Presbytis cristata pullata, subsp. n.

A local race of $P$. cristata, characterized by its darker colouring, especially on the forehead and forearms, and its smaller teeth.

Ilul. Batam and Bintang Islands, Rlio Archipelago. (Type from Batam.)

Type. Adult female. Original number 906. Collectel 12 th July, 1908.

I'en specimens examined.

## (2) Cynopterus (Niadius) harpax, sp. n.

About the same size as C. (A.) minor, Lyon, but the molars, although with the extra cusps typical of Dindius, comparatively narrow and tapering backwards, as in true Cynopterus.

Dimensions of the type : -
Forearm 72 mm . Front of canine to back of $m^{1}$ (alveoli) 10.5 .
$H a l$. Semangko Pass, Selangor, Pahang Boundary.
Type. Male. B.MI. no.8.7.20.7. Original number 571.
(3) Sciurus vittatus nesiotes, subsp. n.

A plantain-squirel most resembling the mainland $S$. v. peninsuluris, from which it differ's by its greyer colouring, less conspicuous lateral stripe, and more brightly coloured hands and feet.

Hab. Batam Island, Rhio Arehiprlago. (T'ype from 'Tanjong Turut.)

Typre. Adult male. Original number 920 . C , $l$ lected 14th July, 1908.

Fitteen specimens examined.
(4) Sciurus vittatus subluteus, subsp. n.

A local form distinguishable from all others by its dingy pale yellow-coloured abdomen. General colouring greyer and teeth smaller than in typical vittatus.

Hab. Si Karang, S.E. Johor.
Type. Adult male. Original number 1250. Collected 1st August, 1908.

Eight specimens from the mainland and one from Tingi Island examined.
(5) Sciurus seimundi, sp.n.

A squirrel allied to and resembling S. rolinsoni, Bonh., but having the dark colour of the back prolonged downwards on the flanks, thus greatly narrowing the broad white ventral area characterizing that species.

Hab. Kundur Island, Rhio Archipelago. (Type from Bliah.)

Type. Old male. Original number 1505. Collected 21 st August, 1908.

## (6) Rhinosciurus peracer, sp. n.

Tail-hairs tipped with buffy ochraceous, white in the geographically neighbouring $R$. tupaioides. Skull with comparatively smali bullee, more as in the Bornean $R$. laticaudutus.

Hind foot of type 41 mm .
Hab. Maxwell's Hill, Perak.
Type. Female. Original number 89. Collected 1st September, 1908.
(7) Rhinosciurus leo, sp. n.

Externally resembling the last, but colours brighter. Specially characterized by its exceptionally large bullæ, which distinguish it from all other forms in the genus.

Hub. Singapore Island and adjacent mainland. (Type from Changi, Singapore.)

Type. Old male. Original number 1122. Collected 24 th July, 1908.

Seven specimens from Singapore and one from the mainland examined.
(8) Rhinosciurus leo rhionis, subsp. n.

A local form of the last, from which it differs hy its larger size, richer general colouring, more evident shoulder-stripes, and more buffy lower surface.

Hal. Rhio Archipelago. (Type from Karimon.)
Type. Adult female. Original number 1366. Collected 13th August, 1908.

Seventeen specimens examined from the islands of Karimon, Kundur, Batam, and Bintang.

## (9) Mus rattus rhionis, subsp. n.

A rat of the albescens type of the rattus group, but darker than any known Malayan form.

Hab. Bintang and Batam Islands, Rhio Archipelago. (Type from Bintang.)

Type. Adult male. Original number 739. Collected 8th June, 1908.

A series of eighteen specimens, of both sexes and all ages, from the two islands examined. The general appearance throughout is very uniform.

## (10) Sus andersoni, sp. n.

A pig of the $S$. vittcius group allied to S. rhionis, but with conspicuously smaller teeth.

Upper length of skull $310 \mathrm{~mm} . p^{2} 10 \times \pm .3 \mathrm{~mm}$. ; $p^{3} 11 \times$ $8 \cdot 3 ; p^{4} 10.3 \times 12$.

Hab. Islands of the Rhio Archipelago. (Type from Batam Island.)

Type. Adult female. Original number 927. Collected 15 th July, 1908.

Four specimens examined.
LVIII.-The Genus Puerulus, Ortmann, und the Post-larval Development of the Spiny Lobsters (Palinurida). By W. 'I. Calman, D.Sc.
(Published by permission of the Trustees of the British Museum.)
The genus Puer was established by Ortmann* in 1891 for the reception of Panulirus cungulatus, Spence Bate, and a new species from Japan described under the name of $P$. pellucidus. I'he genus was distinguished from Senex (=P'oumlirus) by having the antemular segment unarmed and the cephatothoras with a pair of lateral ridges, giving it a mismatic

[^61]instead of cylindrical form. In 1894 the same author * added a third species, P. spiniger, from Amboina, and in 1897 he replaced the preoccupied name Puer by Puerulus $\dagger$. In 1905 Bouvier, overlooking the change in the generic name, described a species, Puer atlanticus, from the Cape Verde Islands $\ddagger$ and Dahomey §. Judging from the very brief description of Bouvier's species, I suspect that it will prove to be identical with Panulirus inermis, described by Pocock || from Fernando Noronha, of which the type is in the British Museum.

Among these species, the first-named, $P$. angulatus, stands apart. Although the type specimen described by Spence Bate fi was only 36 mm . in length of body and was obviously immature, Alcock *\% has since described specimens measuring up to 109 mm . in length, and showing in the males the orifices of the genital ducts. In a female specimen, 164 mm . in length, for which I am indelted to Dr. N. Amandale, Superintendent of the Indian Museum, Calcutta, the orifices of the oviducts are distinctly visible. There can be no doubt that these specimens are adult or nearly so, and that P. anguTatus is a perfectly distinct and independent species, which may be taken as the type of the genus P'uerulus. Alcock, it is true, ignores the genus altogether, and retains the species in the genus Panulirus. It appears to me, however, that Pucrulus, as represented by this species, may well stand as a valid genus, which is probably more closely allied to Limuparus than to Panulirus. It resembles Limuparus not only In the prismatic form of the carapace, but also in the disposition of the pleopods in the female sex ; in P'uerulus and Limurarus the pleopods of the second aldominal somite of the female resemble those of the three fullowing somites, having the endopodite narrow and the appendix interna large; in Pemulirus, as in Palinurus and Jasus, the pleopods of the second somite differ greatly from the succeeding pairs, having the endopodite broad and foliaceous like the exopodite, and the appendix interna reduced to a vestige $\dagger \dagger$.

$\dagger \dagger$ I may take this opportunity of correcting an error in my recently published volume on Crustacea in Sir liay Lankester's 'Treatise in Zoology.' Ou p, 312 the Scyllaridea are defined (follorring must recent

The remaining three species referred to Puerulus ( $P$. pellucidus, $P$. spiniger, and $P$.atlanticus) are all described from specimens of small size (not exceeding 22 mm . length), and this circumstance, together with the slight development of the spines on the carapace and the general thinness of the integument, suggests that they are immature forms. Ortmann has discussed this possibility in describing $P$. spiniger (loc. cit.), which was found together with small specimens of Panulirus versicolor (or, as Ortmann called it, P. polyphagus), and which resembles that species in having no exopodite on the third maxilliped. Ortmann notes, however, that the young specimens of Panutirus did not exceed in size those of Puerulus, although the former had assumed the specitic characters of the adult in the spinulation of the carapace and in other respects; he infers that Puerulus spiniger cannot be the young form of Panulirus rersicolor, and he further concludes that the differences between the two genera are so great that Puerulus, if not an adult, must be the young of some hitherto undiscovered form of Palinurid.

It appears to have escaped notice that these small species of Puerulus agree exactly with Boas's * description of what he calls the "Natant"-stage of the Palinuridæ. Boas found vestiges of exopodites persisting on the thoracic legs of some of his specimens, and he further notes that they retained larval characters in the relative shortness of the antennular peduncle, in having the third maxillipeds separated from each other at the base, and the maxillipeds and maxillæ soft, sparsely setose, and of embryonic appearance. The absence of the "cervical" groove (c), the presence of lateral ridges, and the small number of spines on the carapace are also mentioned, and an important larval character was found in the persistence of coupling-hooks on the appendix interna of the pleopods. The specimens measured up to 25 mm . in length. Boas also mentions that he had examined specimens of young Palinuridx of about the same size as those in the Natant-stage, but agreeing with the adult except in the absence of sexual characters.
authors) as lacking the first pair of pleopods. I overlooked the fact that these appeudages are described as present in the female of Patinureilus by Reas (Kgl. Jauske Vidensk. Selsk. Slir. (6) i. pp. 92 \& 183 (1880), and Zool, Anz. r. p. 113, 118.2) and by Spence Bate (Ann. \& Mag. Nat. Hist. (5) vii. p. 220, 1881). I find that they are also present in a maie specimen belonging to this qeaus in the British Museum collection.
** "Studier orer I eceapodernes slaegtshabstorhold," Legl. Danske Tidensk, Selskr, Skr. (6) i. p. 83 (1880).

## 114 Dr. WV. T. Calman on the Gienus Puerulus and the

Among the Palinuridæ collected by Dr. C. W. Andrews, F.R.S., on his recent visit to Clnistmas Island are five specimens presenting the characters of "Puerulus spiniger," Ortmann. They are all about 2.5 mm . in length of boly, and were collected partly on the reef and partly in crevices in the piles of the pier at Flying-Fish Cove. In all of them the first four pairs of legs have, on the outer side of the basipolite, a soft shrivelled process, which is no doubt the vestige of an exopodite. The antemnular pancle is much shorter than the antemal ; the third maxillipeds are widely separated at the base, and the other mouth-parts are soft, without sete, and imperfectly formed; the appendix interna of the pleopods has an apical group of coupling-hooks. In all these characters the specimens agree with those described by Boas, and I see no reason to dissent from his conclusion that the $g$ represent a late stage, which may. perhaps be called postlarval, in the development of a species of Palinurid.

I believe, however, that it is possible to go further, and to assign these specimens, with considerable confidence, to the species Panulirus rersicolor (Latreille) *. As in the case of the specimens described by Ortmann from Amboina, those of the present collection were found together with young individuals of the species just named, some of which do not exceed the "Puerulus" form in size ( 2.5 mm .). The sinaller specimens of the Punutirus differ from the larger (up to 74 mm . in length) in some small details of structure, e. $\eta$. in laving the antmmular peduncle shorter instead of longer than the antemal, in which they resemble the Pusulus-form. They also differ fiom the larger specimens in the luss brilliant colounge, the bright purple being replaced, in the smaller spirit-specimens, by brown, and the longitudinal striping of the legs being undeveloped. The general pattern of the coloration remains, however, the same. Ortmann deseribes (loc. cit.) the "Jugenlfärbung" (f this species, mentioning especially a $W$-shaped marking on the carapace formed by a longitudimal white band on each side, and a pair of bands converging to the middle line from the hinder ends of these. He notes that in specimens of 26.5 and 13.3 mm . length this pattern was no longer visible. It woull, perhap, be more correct to say that the converging hands lase their impentance as the colour-pattern increases in complexity, althoush they can still be recognized even in very luge specimens. The

[^62]longitudinal lateral bands are always conspicuons. In the general pattern of their coloration the Puerulus-forms agree exactly with the youngest specimens of Panulirus. In three out of the five specimens collected by Dr. Andrews this pattern is very conspicuous, and in the other two, which are much paler, it can still be traced. In all, the ground-colour is a more or less rich brown and the lighter bands and spaces are yellowish or light buff. The lateral longitudinal bands (which do not coincide with the lateral ridges of the carapace) and the convergent bands completing the $W$ are very well marked; the abdominal somites have each a light band posteriorly, with a fainter indication of the narrow marginal dark band seen in the young Pemulirus. Further, if the carapace of one of the more darkly pigmented specimens of the Puerulus-form be examined under a lens, numerous darker spots can be scen, which correspond exactly in their arrangement with the spines on the carapace of a Pomulirus of similar size. These spots no doubt represent the rudiments of the spines in course of development under the semitransparent cuticle.

Boas states that the specimens of the Natant-stage examined by him represented several species belonging to both the longionn and the brevicorn types of Palinuridæ. It does not seem possible at present to refer any of the other "Puerulus" species to definite species of adult Palinuridæ. Perhaps the "Puer atlanticus" of Bouvier ( $=$ "'anulirus inermis, Pocock) may be the young of Panulirus guttatus (Latr.), in company with which it las been found (Pocock, Bouvier), and which it resembles in having a reduced exopodite on the third maxilliped.

In the British Muscum collection are four specimens of a Palinurid in the Natant-stage from Stewart Island, New Zealand, which I suppose to belong to a species of Jasus. These have the general facies of the "Puerulus" forms described above, the integument being soft and semitransparent, the carapace somewhat depressed, with a longitudinal ridge on each side and with a small number of spines anteriorly. There is, however, a well-marked median rostral tooth, which is bent downwards, but does not reach the antenmular segment as it does in the adult Jasus. 'Iraces of exopodites are found on all but the last pair of legs.

The conclusions reached may be summel up as follows:-
(1) Puerulus, Ortmann, 1897 ( $=$ Puer, Ortmann, 1891), is a valid genus of Palinuridx, of which the type species is $P$. angulutus, spence Bate. It agrees with Limuparas,

White, and differs from the other genera of the family in the character of the pleopods in the female sex.
(2) The remaining species assigned to Puerulus, $P$. pellucidus, Ortm., P. spiniger, Ortm., and P.atlanticus, Bouvier ( = Panulirus inermis, Pocock), are foumded on specimens in a stage of development interme liate butween the Phyllosoma and the adult form, called by Boas the "Natant-stage."
(3) Puerulus spiniger, Ortmann, is the Natant-stage of Panulirus versicolor (Latreille), and it passes into the adult form without any perceptible increase of size, while preserving unchanged the gencral pattern of coloration.
(4) Jasus passes through a Natant-stage differing from those which have been referred to $P^{\prime}$ uerulus in possessing a median rostral tooth.
LIX.-Preliminary Nutice of the Ceplaloporta collectell by the Fishery Cruiser 'Goldseeker,' 1903-1908. By E. S'. Russell, M.A., Research Student, University of Glasgow.
The collection of Cuttlefish made by the 'Goldseeker' under the International Committee for the Investigation of the North Sea (Scotland), and entrusted to me by Professor D'Arcy W. Thompson for description, contains representatives of sixteen species, of which three are new. The collections were made on the east and north coasts of Scotland, round the Shetlands, and between the Shetlands and the Faeroes.

Taonidium pfefferi, sp. n.

Polypus faeroensis, sp. n.
The body is very plump and is much larger than the head. There is a distinct constriction between head and body. The breadth of the head is about three-quarters that of the body, its depth about three-fifths.

The colour is a fine reddish purple, of a deep shade on the
back and sides, becoming paler on the rentral surface and on the funnel. The colour is due to minute chromatophores, which are closely crowded together on the dorsal surface of the head, body, arms, and web, more scattered on the ventral surface, and sparsely dotted on the funnel. Chromatophores occur also to a slight extent on the sides of the arms ontside the limit of the web, especially on the inner (dorsal) aspect. Chromatophores are completely absent from the internal (oral) surface of the arms and web, except for a few at the tips of the arms.

The skin is of a firm consistency and there is no lateral fold of the mantle.

The papillation is characteristic. All over the dorsal surface of head, body, and web there are papillary areas; these are more or less circular patches of a lighter colour than the surrounding skin, having in the centre a low conical papilla, while round the periphery stand six or seven smaller papillæ. In a large female these areas are as much as 7 mm . in diameter, and the peripheral papille are distant from the central one; but in two smaller males the areas are smaller and less well defined, aad the peripheral papillæ are set close round the base of the central papilla. The papillæ are whitish in colour, owing to the absence of chromatophores from their tips. These papillary areas are not found at the sides nor on the ventral surface of the web.

Above the eyes, which are small, there is a large conical cirrus, $2-3 \mathrm{~mm}$. high, on which are set a number of small papillæ (much as in some specimens of Polypus arcticus, figured by Verrill). Round the eyes, but not extending to the lower lid, are a number of large papillæ, which may have subsidiary papillæ at their base.

It is not improbable that the "papillary areas" are directly comparable with the papillated cirrus above the eyes. One has only to suppose them erectile to have the homology clearly demonstrated. In the two small males the areas have indeed much the look of half-collapsed papillated cirri.

The ventral surface is perfectly smooth.
The funnel is large, 1.6 cm . long in the smallest male. The free margin below the mantle-flap shows a broad sinus.

The arms are stout and well developed. The order of size is $1,2,3,4$, but the differences are not great. The dorsal arms (measured from the beak) are a little more than three times the length of the mantle (measured dorsally to the eye). There is a strong web which occupies from one-quarter to one-third of the length of the arms. It is more or less equally developed between all the arms, except between the ventral
lair, where it is less developed. The suckers are in two rows slightly alternating, and are perfectly formed, though small, at the extreme tips of the arms. Near the mouth three or four suckers stand in a single row. There are about 60-70 suckers on each arm of the large female, and the largest of them measures 4 mm . in diameter.

The hectocotylisation closely resembles that of $P$. areticus, but it is, relatively to the leugth of the arm, very much smaller. Thus it measures 14 mm . in length on an arm measuring 11.4 cm . The calamus brachialis is small and triangular, the ligula copulatoria is broadly oval and comes to a blunt point. There are $11-13$ ridges on the ligula. The hectocotylised arm is little shortened; the web is developed especially on the ventral side; there is a sperm-canal ( 21 mm . long) running down the ventral edge of the web to midway between the third and fourth arms.

I give below the dimensions of a large female and of a male :-

Dimensions (in cm.).

'The hectocotylised arm of the male measures 114 cm . in length, of which 10 cm . bear suckers (to the number of 40 ). The hectocotylised part is 1.4 cm . long and 9 mm . broad. The ligula bears 13 transverse ridges.

Polypus fueroonsis is fairly closely allied to $P$. arcticus (Prosch), but it differs in certain well-lefined ways. The body is not so broad, and the distinction between head and body is very much better marked. The arms are longer in proportion to the body. The hectocotylised arm is much longer and the hectocotylised part much shorter than in $P$. arcticus (Octopus bairdii of Verrill), in which the hectocotylised part is one-third the length of the arm. Finally, the papillation is distinctive.

In a large female of $P$. areticus, measuring in overall length 17 cm ., the breadth of the mantle was 5.5 cm ., of the head 4.1 cm ., while the longest arm was only 12.5 cm . in length (Verrill, Rep. U.S. Comm. Fish. for 1879 (1882), p. 395, pl. xli. figs. 1, 2, 3 a, pl. xlii. figy. 1-5). In a large male ( 16.3 cm . overall) the hectocotylised arm was 8.5 cm ., the hectocotylisation 3.3 cm . long.

With the North Atlantic species, P. ergasticus (Fischer), P. sponsalis (Fischer), and P. profundicola, Massy, thi; species shows no points of special similarity.

One large female and two smaller males were taken by the 'Goldseeker' on Aug. 24th, 1908, in 1030 m. at Sta. 19 A (Faeroe Chamnel), associated with half a dozen specimens of $P$. piscatorum (Verrill).

## Brachioteuthis bowmani, sp. n.

The body is fusiform and runs out into a sharp point behind. The anterior border of the mantle is free all round, almost straight or slightly convex above, not produced in an obtuse angle. At the sides, just above the level of the lower border of the eye, the mantle-border projects slightly, the mantle-cartilage, which articulates with the funnel, running to the end of this projection.
The pen is clear brown in colour and is plainly visible along the mid-dorsal line, where it is 1 mm . broad. At the insertion of the fin it broadens out and the margins bscome folded down ; near the tip the margins fuse to form a hollow cone, 11 mm . in length and 2 mm . in breadth at the base.

The fin resembles in shape that of Ommatostrephes sayittatus. It occupies the posterior third of the mantle.
The funnel is rather broad and is free only at the tip. The hinder margin is thin and shows a shallow sinus. The comnective cartilage exhibits a longitudinal groove, 7 mm . in length, slightly enlarged at the posterior end. The comnective on the mantle is a linear ridge, 10 mm . in length.

There is a pair of long and broad adductor muscles.
The sides of the fumnel run up as broad bands to the middorsal line, where they fuse with the neck. At the line of fusion there is a longitudinal horny piece with two lateral grooves like those of the connective cartilage on the fumel. This piece is 6.5 mm . long and lies directly below the front end of the pen, whose incurved margins articulate with the grooves.

The head is very large, with enormons eyes. It is broader than the mantle-opening.
Ann. \& Mag. N. Hist. Ser. 8. Vol. iii.

The actual visceral sac is very small, being narrowly triangular and not extending back much beyond the insertion of the fins. The gills are very long and slender.

The mantle is covered with small pale red chromatophores, which are present also on the dorsal aspect of the fins. The head is more deeply coloured in shades of brown and crimson, the chromatophores being aggregated especially at the anteroventral border of the eye. The eye is covered over by a skin set with chromatophores and resembling the skin of the head. In front there is a deep transverse groove with puckered edges; it is 3 mm . long, has a muscular margin, and marks the opening from the anterior chamber of the eye to the exterior.
Chromatophores are present also on the arms and tentacles.
The order of the arms is $2,3,4,1$. They are without web or keel, except the ventral pair, which have a narrow fin on their extero-ventral edge. The second pair are about trothirds the length of the mantle. The suckers are in two slightly alternating rows, and they are not continued right down to the mouth, $2-3.5 \mathrm{~mm}$. being without suckers. The cups of the suckers are nearly globular, inserted very obliquely on pedicels, slender above, swollen below. The horny ring is higher above, has $5-8$ square teeth on its upper half, and is smooth on its lower half.

On the second and third arms, and to a less extent on the first arms also, the swollen part of the pedicels of the external row of suckers gives off a slender cirrus, whose length may equal the diameter of the cup. The cirri are not free, but are bound to the arm throughout their length by a fold of thin skin. Tentacles are fairly stout, 60 mm . in length, more or less triangular in cross-section. The club is 13 mm . long, 5 mm . broad, and is thin and flattened from above downwards for 10 mm . of its length, then at the tip the plane of the club is twisted inwards through a right angle, so that its ventral surface becomes vertical and looks inwards. This terminal part is 4.5 mm . long and has a thin vertical suckerless crest. The axis of the tentacle is not itself expanded to form the club, the lateral portions of which are formed rather by the long pedicels of the marginal suckers, which are bound together in a membranons expansion of the axis. In the terminal portion the axis is without suckers, but its ventral expansion bears three rows, of which the lowest are the largest. At the twist of the club there are two irregular transverse rows of large suckers, about five suckers in each row. These are the largest suckers on the club. The main body of the club bears on its ventral surface numerous thinstalked minute suckers irregularly disposed in about 12-15
rows. Towards the proximal end of the club the suckers stand in fewer rows. Sessile suckers extend in about four scattered rows halfway down the internal face of the tentacle; these are very minute and become very sparsely scattered as they reach the middle of the tentacle.
'I'he cups of the suckers on the club are hemispherical and the horny ring bears in its upper half fine pointed teeth.

There is a well-developed buccal membrane with about eight ill-defined angles.

A single specimen, apparently a female, was taken on June 9th, 1908, at Sta. 15 c in 778 m .

This species, which is named after Dr. Alex. Bowman, naturalist on board the 'Goldseeker', is very close to the only other species of the genus, $B$. beanii, Verrill. It is described as new because it seems to offer several points of difference and because it does not resemble at all closely Verrill's figures (Rep. U.S. Comm. Fish. for 1879 (1882), p. 424, pl. xlv. figs. $3-3 b$, pl. xlvi. figs. 2, 2 a). The great size of the eyes, the pigmented cornea, the shape of the anterior margin of the mantle, the peculiarities in the structure of the suckers and of the tentacular club seem to warrant its separation from Brachioteuthis beanii.

## Taonidium pfefferi, sp. n.

The body is flattened dorso-ventrally. It is oval in outline, the sides curving in sharply at the posterior end, where the terminal part of the pen rums out, fringed by the small fins, which together form a broad ellipse. This terminal portion is 3 mm . long by 2.7 mm . broad. The tip of the pen extends a very liitle way beyond the fins. The length
of the mantle mid-dersally to the insertion of the fins is 16.5 mm . ; its greatest breadth is about halfway along the back, where it measures 115 mm . In front the dorsal edge of the mantle is transverse, with a sinuous margin, and measures 6.5 mm . across. It is distinctly proluced at the corners and curved sharply back in the middle line, where it is fused with the head. The ventral margin of the mantle exhibits two deep bays laterally where it is fused with the siphon, and in the middle it is produced forward in a small flap-like process. The mantle is very delicate and translucent, of a clear whitish tinge in formalin, probably quite transparent during life. On the back there are a few oval chromatophores of large size (up to 2 mm .) : one is situated at the fusion of mantle and neck, and along the lateral margins there are about five on each side. On the ventral surface the chromatophores have a similar arrangement-a pair opposite the base of the fumel, a pair behind and external to these, then two or three on each lateral margin, and three or four near the base of the tail.

The organs of the body seem confined to the anterior twothirds of the mantle-sac. The musculature is reduced. In the posterior third there are delicate transverse bands or hoops of muscle; the anterior two-thirds are more muscular.

The neck and head are continuons and very narrow; the distance from the mantle to the circle of arms is 3 mm ., and the head is only slightly swollen at the insertion of the large stalked eyes. It is only 1.4 mm . broad below the arms. In the median line dorsally are two chromatophores, and another lies close below the origin of the first pair of arms. Ventrally the funnel covers over another small chromatophore.

The eye-stalks are very large, 3 mm . in length, 1.8 mm . broad in the middle, while external to their insertion on the head they exhibit a swelling. There is a large and conspicuous squarish chromatophore on the dorsal surface of each stalk, red round the edges, but appearing dark in the centre owing to the pigment of the eye shining through. The eyes show iridescent pigments-red, yellow, green, purple, and dark blue.

The fumel is large and reaches forward to about half the length of the eye-stalks. It measures $4 \cdot 5 \mathrm{~mm}$. across at its base.

The arms form a circle round the mouth, which in this specimen protrudes a little and is surrounded by a thick frilled sheath. The arms are very small, and are unwebbed and without fins. The two lateral pairs are the largest. The lengths of the arms are 2 mm ., 2.5 mm , 2.7 mm , and

2 mm . The suckers are in two irregular rows and have a smooth horny ring.

The tentacular arms are long ( 17 mm .) and stout, not expanded distally to form a club. On the terminal 3.5 mm . there are four rows of subequal suckers, which bear mostly a few irregular blunt teeth on the upper half of their horny ring. All along the ventral aspect of the stalk there are $2-3$ rows of very small suckers. These are not too well preserved, but they seem to have had minute cups and delicate stalks.

There are half a dozen chromatophores on the back of the "club" and one or two on the back of the stalk. The pen is apparently very delicate, being clearly visible only at the posterior end between the fins, where it forms a cone. It is traceable up the mid-dorsal line as a transparent streak.

A single specimen was taken on Ang. 31st, 1907, in $60^{\circ} 3^{\prime}$ N., $3^{\circ} 53^{\prime}$ W., in 505 m . It is, however, very probably a surface form.

Taonidium pfefferi is not unlike Taonidium summi (Lankester), and, indeed, Dr. Hoyle, who examined the specimen, put it down to that species. Dr. Pfeffer, however, was of opinion that the specimen was specifically distinct, and examination of the question has led me to share his opinion. It differs from Taonidium suhmi in its broader shape, in the order of the arms, structure of tentacle-stalk, arrangement of chromatophores, and in the outline of the anterior mantlemargin. In T. sulmi (Hoyle, Chall. Rep. xvi. (1886) p. 192, pl. xxxii. firs. $5-11$ ) the body is fusiform, with the length more than three times the breadth; the order of the arms is $4,3,2,1$, there are no suckers on the stem of the tentacles, the chromatophores are in about eight rows, and the mantle-margin is straight.

In some respects Taonidium nfefferi approaches close to the genus Owenia, Pfeffer, with its single species Owenia megalops (Prosch); but the two genera are probably hardly distinct from one another.
'The species is named in honour of Dr. Georg Pfeffer, Hamburg.

## Moschites cirrosa (Lamarck).

Examination of specimens from Naples and from Plymouth has convinced me of the identity of the common 11. cirrosa of our shores with the Mediterranean M. aldrovandi. Among the specimens of Moschites collected by the 'Goldseeker' there are two distinct types-one the true aldrovandi form, with its reddish colour and its arms all closely bound
together to form a deep conical "umbrella-cavity"; the other a greyish form, with the arms connected up by a loose web, so that the "umbrella-cavity" is very flat and open. The latter form seems to occur chiefly in the north of Scotland and in the Shetlands. I hesitate to assign to it specific rank, but it will be described and figured in the complete account as a new variety.

The majority of the specimens were females, but one or two small males also occurred. One male of the aldrovandi type showed a small hectocotylisation exactly resembling that figured by Jatta for M. aldrovendi. I have had an opportunity of examining also a male of this same type, 11 cm . in length, in the Maseum of Cniversity College, Dundee. It had been taken at Aberdeen in October 1893, and showed quite clearly the hectocotylisation typical of 1\%. aldrovandi. One small male belonging to the other form of $M$. cirrosa showed a slight hectocotylisation of the same general character. In no case did I observe the paired cirri on the tips of the arms of the male which are described by Steenstrup and by Posselt as distinctive features of M. cirrosa. There can be no doubt, I think, that Lamarck's Octopus cirrhosus and Rafinesque's Jiledone aldrovandi are identical, and that the Eledone cirrosa described by Steenstrup and by Posselt is quite a different species, probably a northern form.

It is unfortunate that the rule of priority demands the naming of our common British species Moschites cirrosa, when the identical Mediterranean form has been so beautifully described and figured by Jatta under the name of Moschites aldrovandi.

## Rossia glaucopis, Lovén.

This is distinctly a northern form, being recorded from the Norwegian coast, Spitzbergen, Greenland, and in British waters hitherto only fiom the shetlands and (as $R$. sublevis) from 250 fath. to the south-west of Ireland (smith). It was taken by the 'Goldseeker' chiefly in deep water in the Faeroe Channel and near the Shetlands, but one small specimen was taken in 200 m . as far south as Kinnaird Deeps. Eggs of this species, imbedded in a mass of soft sponge and containing the remarkably large embryos ( $6-7 \mathrm{~mm}$. long), were taken in 110 m . at $60^{\circ} 23^{\prime} \mathrm{N}$., $0^{\circ} 14^{\prime} \mathrm{W}$.

S'epiola aurantiaca, Jatta.
This is undoubtedly a good species of Sepiolu. About
twenty specimens were taken at various localities on the east coast of Scotland, near Shetland, and in the Faeroe Channel, which agree closely with Jatta's descriptions and figures. The only point of difference which should be mentioned is that the two adult males in my possession show foliaceous processes at the base on the first left arm only. Jatta describes these as occurring to a slight extent on the first right arm also. The distinctive characters of this beautiful species are the full red colour of the back, due to the numerous small and crowded chromatophores, the deeply sinuous outline of the inferior margin of the mantle, the deeply incut fins, and in the male the foliaceous hectocotylisation. The tentacular club bears in my specimens $8-10$ rows of small suckers.

Sepiola aurantiaca has hitherto been recorded only from Mediterranean waters.

## Calliteuthis reversx, Verrill.

T'wo small examples of this remarkable species were taken with the Petersen young-fish net at Sta. $59^{\circ} 5 t^{\prime} \mathrm{N} ., 7^{\circ} 6^{\prime} \mathrm{W}$. , in 250 m . They are only $1 t \mathrm{~mm}$. and 17 mm . in length. They lack the dark brown colour inside the arms, on the buccal membrane, and along the edge of gill, which Verrill describes for this species, but they show the typical arrangement of the luminous organs on the ventral surface and on the ventral and ventro-lateral arms. Dr. G. Pfeffer, who very kindly examined my specimens of Oigopsida, has confirmed this identification.

Calliteuthis reversa has not previonsly been recorded from British waters. Verrill records it from the deep water of ${ }^{\text {n }}$ the north-eastern coast of America in 365-2369 fath. It has been found in New Zealand and Japanese waters (Hoyle) and also in the Mediterranean (Pfeffer).

The collection was worked over in the Embryological Laboratory of Glasgow University during the winter sessions 1907-8 and 1908-9. A full account of the collection, with figures of the new species, will appear in comexion with the 'Reports of the North Sea Fisheries Investigation Committee (Northern Area).'

March 1909.

## BIBLIOGRAPHICAL NOTICE.

## A Naturatist in Tasmania. Ry Geoffrey Smitr, M.A. Oxford: The Clarendon Press. 1909.

Mr. Geofrrey Suith, a Fellow of New College, Oxford, in this most delightful book has set down the results of a six-months' survey of Tasmania, carried out during the spring and summer of 1907-8. The expedition was undertaken at the suggestion of Prof. G. C, Bourne, the Linacre Professor of Comparative Anatomy at Oxford, and the aim thereof was to sursey the freshwater fauna of Tasmania. The Author has done this, and much more, and in these pages the results of his trip are set forth after a most charming and lively fashion.

A fortnight was spent in dredging worls on the Great Lake and incursions iuto the surrounding bush. This lake has earned a considerable reputation among fishermen for the size and number of the trout which it contains ; and this is not surprising; for these trout are giants, scaling $2 . \overline{\text { in }}$ pounds. They are, the Author remarks, the " ordinary English Brown Trout," introduced in 186.t, which, by dint of good liring and freedom from enemies, have nothing to do but wax and grow fat-which they do, haring a superabundance of ground food in the shape of small C'rustacea. But this dict can be raried at will, since the lake abounds with two species of natire trout belonging to the genus Galaxias, which, strimmiug in large shoals, afford an easy prey to the alien race.

Of the Crustacea Mr. Geoffrey Smith had the good fortune to find a new form of the rery remarkable ground-shrimp (Anaspinites tusmanice), common at a high eleratiou on Mnunt Wellington and in clear tarns on Mount Field and the Marz Mountains. This new form, to which he has given the name Puranaspirles lucustris, differs conspicuously from the typical Anctspiles, and appears to be more of a free-swimming type and confined to the Great Lake. Here also he found sereral species of the peculiar Crustacean genus Phreatoicus. Sereral distinct species of the genus occur here and in great abundance. This genus is "confined to the alpine regions of Southern Australia and New Zealand." These two genera, it would seem, stand in the same relation to other Crustacea "as the Platypus does to ordinary Mammals."

Of the Giant Crayfish (Astucopsis fromlilinii), the largest freshwater craytish in the world, some interesting facts are given here. All the specimens he found were "smothered with a parasitic flatworm (Temnoceplucta) about a quarter of an inch long," and erowded together "in such numbers as to appear like a green foam covering the animal."

Of the larger and more interesting mammals, the Thylacine and the Dasyure, he has much to say that is worth reading, if not new. The Thylacine, at any rate, appears to be on the verge of extinction.

But as to these, and much more, we must refer the reader to the book itself, which is in every way a most entrancing volume.
IV. P. P.

## THE ANNALS

## AND

## MAGAZINE OF NATURAL HISTORY.

[EIGHTH SERIES.]

No. 18. JUNE 1909.
LX.-Descriptions of some new Species of Heterocera, chiefly from Tropical South America. By Herbert Druce, F.L.S. \&c.

## Fam. Syntomidæ.

Bombiliodes simulans, sp. n.
Female-Head, palpi, antennæ, collar, tegulæ, thorax, and abdomen black, the sides of the abdomen green, the base of the abdomen white; legs black, spotted with white. Primaries black, the cell and a streak below the cell hyaline, the fringe black: secondaries black, hyaline at the base. The underside of both wings the same as above.

Expanse 1 $\frac{1}{2}$ inch.
Hab. Cayenne (Mus. Druce).
Napata boettgeri, sp. n.
Male.-Head, palpi, and antennæ black, front of head spotted with white; collar bright carmine; tegulæ and thorax black; abdomen metallic blue; the underside of the thorax and abdomen white; legs black. Primaries black, the apex white; a large square hyaline spot at the end of the cell and two hyaline spots beyond the cell nearest the anal angle; the fringe at the apex white, on the outer margin

Ann. \& Mag. N. Hist. Ser. 8. Vol. iii.
black: secondaries hyaline white, broadly bordered with black; the fringe black. Underside very similar to the upperside, but with wings shot with bright blue.

Expanse $1 \frac{1}{2}$ inch.
Hab. E. Peru, Huancabamba, 6000-10,000 feet (Boettger, Mus. Druce).

Allied to Napata cincticollis, Felder, from which it differs in having the spots white instoad of yellow and the apex of the primaries white.

## Correbia flavata, sp. n.

Mate.-Head, antennæ, palpi, abrlomen, and legs black, the legs banded with white ; back of the head, collar, tegulæ, and thorax orange-red. Primaries orange: secondaries black, slightly hyaline at the base. Underside of both wings black, the base and costal margin of the primaries orange-red.

Expanse $1 \frac{3}{4}$ inch.
Hub. W. Culombia, San Antonio, 500 feet (G. M. Pulmer, Mus. Druce).

## Fam. Arctiadæ.

## Idalus viridis, sp. n.

Mate.-Head, collar, tegulæ, and thorax pale green; the palpi and underside of the thorax red; antennæ black; abdomen and legs red. Primaries pale green, the costal margin yellow; two small black streaks on the margin ; the fringe green : secondaries pale green, the imer margin and anal angle red; the fringe greenish white. The underside very similar to the upperside.-Female like the male, but considerably larger.

Expanse, $\delta 1 \frac{1}{4}$, if $1 \frac{3}{4}$ inch.
Hab. E. Peru, Chanchamayo, 2000-7500 feet (Mus. Druce).

## Automolis rosa, sp. n.

Female.-Head yellow, palpi red, collar pink; tegulæ yellow, edged with pink; thorax and abdomen pale yellow; abdomen clothed with pink hairs at the base ; antenne black, yellow at the tips; legs pale yellow. Primaries pink, the costal margin from the base to the middle yellow; a wide yellow band crosses the wing about the middle from the costal margin to the inner margin; the outer margin broadly yellow; the fringe rellow: secondaries pale cream-colour,
slightly shaded with pink on the inner margin ; the fringe cream-colour. Underside very similar to the upperside.

Expanse 2 inches.
Hab. W. Colombia, San Antonio, 5800 feet (G. M. Pulmer, Mus. Druce).

## Opharus palmeri, sp. n.

Male.-Head, collar, tegule, thorax, and base of abdomen orange-brown; the tegulæ edged with dark brown; palpi and antennæ black; abdomen black, banded with orangebrown; the anus yellow; legs dark brown. Primaries dark brown, thickly streaked with fine orange-coloured lines; the veins orange-brown; the fringe dark brown: secondaries blackish brown, whitish at the base. Underside dark brown, the costal margin and apex of the primaries orange-yellow.

Expanse $2 \frac{1}{2}$ inches.
Hab. W. Colombia, San Antonio, 5800 feet (G. M. Palmer, Mus. Druce).

This species is allied to Opharus rhodosoma, Butler.

## Fam. Noctuidæ.

Subfam, Acronyctinat.
Macronoctua dolens, sp. n.
Male.-Head, collar, tegulæ, and sides of thorax dark grey; antenne black, the centre of the thorax and the sides of the abdomen silvery grey; the centre of the abdomen and anus dark blackish grey; the legs, underside of the thorax, and abdomen dark grey. Primaries very dark blackish grey, the apex and inner margin pale silvery grey; several very fine black waved lines cross the wing from the costal to the inner margin; the fringe dark grey: the secondaries pure semihyaline white, the veins black at the apex. Underside : primaries greyish white, darkest along the costal margin: secondaries as above.

Expanse $2 \frac{1}{2}$ inches.
Hal. E. Peru, Huancabamba, 6000-10,000 feet (Bottger, Mus. Druce).

Allied to Macronoctua onusta, Grote, from North America.
Calymniodes acamas, sp. n.
Male.-Head, collar, and tegulæ reddish brown, speckled with minute white dots; antenne dark brown; thorax and
upperside of the abdomen dark brown; underside of the thorax, abdomen, and legs pale reddish brown, the legs speckled with white. Primaries dark brown ; a large silverwhite spot at the base of the cell; a white streak below the basal spot and three small silvery-white dots at the end of the cell; a double row of small black spots cross the wing from near the apex to the middle of the inner margin ; a waved reddish-brown line extends from the apex to the anal angle; a marginal row of small greyish spots extends from the apex to the anal angle; the fringe dark brown: secondaries palc brown, palest at the base; a dark brown spot at the end of the cell; the fringe pale brown.-Female very similar to the male, but paler in colour.

Expanse $1 \frac{1}{4}$ inch.
Hab. Bolivia (G. Garlepp, Mus. Druce).

## Geroda leucocycla, sp. n.

Femate.-Head, antennæ, collar, tegulæ, therax, abdomen, and legs pale brown. Primaries pale reddish brown, crossed from the costal to the inner margin by three waved whitishbrown lines edged with black dots; a white spot at the end of the cell ; the fringe dark brown : secondaries dark brown, the marginal line pale reddish brown.

Expanse $1 \frac{1}{4}$ inch.
Hab. Colombia, Minca, 2000 feet (II. H. Smith, Mus. Druce).

## Subfam. ERAStridive.

## Mictochroa albirena, sp. n.

Female.-Head, collar, tegulæ, thorax, and base of abdomen greenish white ; abdomen pale brown ; antennæ black; legs black, banded with white. Primaries brown, greenish at the base; a large white spot at the end of the cell irrorated with greenish scales ; the anal angle and part of the outer margin white; the fringe pale brown: secondaries blackish grey, the fringe grey. The underside of both wings blackish grey.

Expanse $1 \frac{1}{10}$ inch.
Hab. Colombia, Sierra del Libane, 6000 feet (H. H. Smith, Mus. Druce).

## Mictochroa harmonica, sp. n.

Male.-Head and antennæ brown; collar, tegulæ, and thoras pale brown, thickly irrorated with white scales and hairs; the base and underside of the abdomen grey; the upperside of the abdomen brown; the legs brown, banded with white. Primaries dark brown, irrorated with purplishgrey scales at the base ; a waved black line crosses the wing from the costal to the inner margin; a large pale brown spot edged with white at the end of the cell, beyond which a pinkish-green curved line crosses the wing; the marginal line spotted with black; the fringe alternately brown and white: secondaries pale brown, with a submarginal dark line extending from the apex to the imer margin; the fringe pale brown.

Expanse $1_{1}^{3}{ }^{3}$ inch.
Hab. Colombia, Sierra del Libane, 6000 feet (H. II. Smith, Mus. Druce).

## Mictochroa thermoptera, sp. 11.

Male.-Head, collar, tegulæ, thorax, and abdomen reddish brown; palpi red; antennæ black; underside of abdomen and legs pale brown. Primaries red-brown, crossed about the middle from the costal to the inner margin by a wide dark brown band, edged on the outer side by several very indistinct, narrow, waved, greyish-white lines; a large reddish-brown spot on the costal margin close to the apex; the fringe red-brown: secondaries blackish grey; the fringe red.

Expanse $1 \frac{1}{2}$ inch.
Hab. S.E. Peru, Santo Domingo, 6000 feet (G. Ockenden, Mus. Druce).

## Chalenata ustota, sp. n.

Male.-Head, antennæ, collar, tegulæ, thorax, abdomen, and legs brown. Primaries sordid white, thickly irrorated with brown scales at the base of the wing; a wide dark brown band crosses the wing about the middle from the costal to the inner margin ; the outer margin spotted with black; the fringe brownish white: secondaries brownish white, with marginal black spots ; the fringe white.

Expanse 1 inch.
Hab. Colombia, Ninca, 2000 feet (II. II. Smith, .1us. Druce).

## Eublemma rhodocraspis, sp. n.

Female.-Head, collar, tegulæ, thorax, abdomen, and legs white. Primaries white, shaded along the costal margin with vesy pale fawn-coloured scales; a large elongated fawncoloured spot at the anal angle; the fringe very pale fawncolour: secondaries white, very broadly bordered with fawncolour from the apex to the anal angle; a few black scales near the anal angle ; the fringe pale fawn-colour.

Expanse 1 inch.
Hab. Bomeo, Elopura (Pryer, Mus. Druce).

## Tarache micropis, sp. n.

Mate.-Head, collar, tegulæ, thorax, abdomen, and legs white; antemme pale brown. Primaries: the base and costal half of the wing white, crossed by bluish-grey lines; a small round black spot at the end of the cell ; the apex and outer half of the wing greyish brown; the fringe brown and white: secondaries pure white, slightly dusky at the apex. Underside very similar to the upperside, but paler in colour; the costal margin of the primaries blackish brown.

Expanse 1 inch.
Hab. Parana, Castro (E. D. Jones, Mus. Druce).

## Tarache ochrochroa, sp. n.

Male-Head, collar, tegulæ, thorax, abdomen, and legs yellowish white; antennæ black. Primaries yellowish white, clouded along thie costal margin and at the base with pale brown ; a broken wide brown band irrorated with bluishwhite scales crosses the wing from the apex to the inner margin nearest the anal angle; the marginal line spotted with black dots; the fringe yellowish white and black: secondaries yellowish white, the fringe the same colour.

Expanse 1 inch.
Hab. Brazil, Goya (Perrens, Mus. Druce).
Tarachidia semilrunnea, sp. n.
Male.-Head, collar, tegulæ, thorax, and abdomen white; antennæ black; legs brown, banded with white. Primaries: the basal half white, crossed from the costal to the inner margin by a narrow brown line; the apical half of the wing brown, with a whitish spot on the costal margin close to the
apex; the fringe dark brown: secondaries white, clouded with pale brown near the apex ; the fringe pale brown. The underside very similar to the upperside, but the brown on the primaries much paler.

Expanse $\frac{3}{4}$ inch.
Hab. Paraguay (W. Reeve, Mus. Druce).

## Erastrioides alliguttata, sp.n.

Male. - Head, collar, tegulx, thorax, and abdomen greenish white; antennæ and palpi black; legs black, banded with white. Primaries pale olive-green, pinkish at the base; a small spot in the cell, one below the cell, and a large elongated spot at the end of the cell ; a large angularshaped spot on the inner margin close to the apex all white; a rather wide dark brown submarginal band crosses the wing from the apex nearly to the anal angle; the fringe alternately black and pale olive-green : secondaries sordid white, the apex, outer and inner margins clouded with dusky brown. The underside dusky grey.

Expanse 1 inch.
Hab. S.E. Peru, Santo Domingo, 6000 feet (G. Ockenden, Mrus, Druce).

## Parangitia veluta, sp. n.

Male.-Head and palpi dark brown ; collar and tegulæ dark brown, thickly irrorated with greyish hairs; thoras and abdomen pale fawn-colour; anal tuft black; antenus pale brown ; legs dark brown. Primaries very dark brown, with a large black mark across the wing near the apex; the fringe dark brown: secondaries dark brown, palest at the base. The underside of both wings dark brown.

Expanse $1 \frac{1}{2}$ inch.
Hab. Peru, La Oroya, Carabaya, 3000 feet (G. Otlienden, Mus. Druce).

## Parangilia rufa, sp.n.

Male.-Head, palpi, collar, tegulæ, thorax, and abdomen reddish brown ; antennæ black ; legs dark brown. Primaries dark brown, irrorated with lighter brown scales near the base; a minute white dot at the end of the cell and some waved black streaks near the anal angle; the fringe dark brown: secondaries dark brown, the fringe alternately light and dark brown. Underside: primaries dark brown, palest
at the apex and along the outer margin: secondaries unim formly dark brown.

Expanse $1 \frac{1}{2}$ inch.
Hab. S.E. Peru, Santo Domingo, 6000 feet ( $G$. Ockenden, Mus. Druce).

## Parangilia cana, sp. n.

Female.-Head and palpi reddish brown; collar grey; tegulæ, thorax, and abdomen pale brown, thickly irrorated with grey scales and hairs; lega reddish brown. Primaries pale reddish brown, thickly irrorated with grey scales; a distinct black spot at the end of the cell; a dark brown patch beyond the cell ; a reddish-brown patch at the apex and anal angle ; the fringe alternately pale and dark brown: secondaries dark blackish brown, palest at the base; the fringe pale brown.

Expanse $1 \frac{1}{4}$ inch.
Hab. S.E. Peru, Santo Domingo, 6000 feet (G. Ockenden, Mus. Druce).

## Parangilia virescens, sp. n.

Female-Head, collar, tegula, thorax, and abdomen brownish grey ; antennæ and palpi black; legs dark brown, banded with pale brown. Primaries dark brown, the basal half of the wing heavily spotted with bright green; three small black dots in the cell; a white spot at the end of the cell; a black streak and dot beyond the cell; four green spots on the outer margin close to the anal angle; the fringe alternately green and brown: secondaries dark brown, the fringe pale brown.

Expanse $1 \frac{1}{4}$ inch.
Hab. S.E. Peru, Santo Domingo, 6000 feet (G. Ockenden, Mus. Druce).

Angitia albirufa, sp. n.
Female.-Head, palpi, collar, tegulæ, and thorax dark red-brown; abdomen paler brown; antennæ black; legs dark brown, banded with greyish white. Primaries dark reddish brown; the anal angle and half the outer margin fawn-colour; an indistinct spot at the end of the cell paler brown: secondaries black, the fringe reddish brown.

Expanse 1 inch.
Hub. S.E. Pern, Santo Domingo, 6000 feet (G. Ockenden, Mus. Druce).

## Paracodia albiceps, sp. n.

Male.-Head, palpi, and collar fawn-colour; tegulæ, thorax, and abdomen dark brown; antennæ and legs brown. Primaries dark brown, crossed from the costal to the inner margin by two waved reddish lines, the first near the base, the second beyond the cell, the marginal line dotted with black; the fringe dark brown: secoudaries brownish white, thickly irrorated at the apex with brown scales; the marginal line dotted with black; the fringe brownish white.

Expanse $\frac{3}{4}$ inch.
Hab. Colombia, Valparaiso, 4500 feet (II. H. Smith, Mus. Druce).

## Fam. Lasiocampidæ.

Ormiscodes mota, sp. n.
Male-Head, collar, tegulæ, and thorax orange-yellow; palpi black; antennæ pale yellow ; legs black, clothed with yellow hairs; abdomen black, each segment edged with white; the anal tuft orange-yellow. Primaries red, the costal margin edged with black; a large >-shaped white mark, edged with black on the upperside, at the end of the cell; the veins all yellow; the fringe yellow: secondaries red, the veins yellow, the fringe white. Underside very similar to the upperside, but rather darker in colour; the costal margin of the secondaries white, below which is a broad black line from the base to the apex.

Expanse $3 \frac{1}{2}$ inches.
Hab. W. Colombia, San Antonio, 5800 feet (G. M. Palmer, Mus. Druce).

This species is allied to Ormiscodes raduma, Druce, from S.E. Peru.

## Fam. Notodontidæ.

## Poresta striata, sp. n.

Female.-Head, antennæ, palpi, collar, tegulæ, and thorax black-brown ; abdomen above dark brown; underside and legs reddish brown. Primaries dark brown, thickly striated with fine black lines; a fine pale brown line crosses the wing from the apex to the middle of the inner margin ; the fringe
dark brown: secondaries reddish brown, the fringe pale brown. The underside of both wings brown.

Expanse 2 inches.
Hab. E. Peru, Huancabamba, 10,000 feet (Bretlger, Mus. Druce).

## Poresta albonotata, sp. n.

Male.-Head, palpi, collar, and tegulæ black ; antennæ black; thorax and upperside of abdomen reddish brown, the sides of the abdomen black; a white line extends from the base to the anus, which is thickly clothed with black hairs; the underside of abdomen and legs reddish brown. Primaries reddish brown, striated with fine yellowish lines; a large white spot at the base; a white line crosses the wing from the apex to the middle of the inner margin ; a wide greyish line extends from the base to the anal angle ; the fringe dark brown: secondaries red-brown, palest at the base; the fringe white. Underside of both wings brown, thickly irrorated with grey scales.

Expanse $2 \frac{1}{4}$ inches.
Hab. S.E. Peru, Santo Domingo, 6000 feet (G. Ockenden, Mus. Druce).

## Lepasta argentilinea, $\mathrm{sp} . \mathrm{n}$.

Male.-Head, palpi, antennæ, collar, tegulæ, and thorax brown; tegulæ and thorax streaked with pale yellowish brown, the base of the thorax dark brown; abdomen and legs reddish brown. Primaries dark brown, the costal margin pinkish, with a silver line extending from the base to the apex; a submarginal line extends from the apex round the outer margin to the anal angle and from the anal angle to the base ; three silvery streaks cross the wing, almost reaching the outer submarginal line; the marginal line yellow ; the fringe dark brown: secondaries pale brown, palest at the base and along the imner margin ; the fringe pale yellowish brown. Underside pale brown, with a marginal row of black spots on the primaries.

Expanse $1 \frac{1}{2}$ inch.
Hab. S.E. Peru, Santo Domingo, 6000 fect (G. Oclienden, Mus. Druce).

Allied to Lepasta grammodes, Felder.

## Dicentria florella, sp. n.

Male.-Head, collar, and thorax olive-green; antennæ
pale brown; tegulæ white ; abdomen black; the underside and the legs grey. Primaries white, crossed near the base from the costal to the inner margin by a wide olive-green band, elged with black on the inner side; this band narrows in the middle; an elongated olive-green spot on the costal margin near the apex; the fringe green and white: secondaries white, shaded with brown at the apex and along the inner margin. Underside of both wings white, the costal margin of the primaries pale brown.

Expanse $1 \frac{1}{2}$ inch.
Hab. S.E. Peru, Santo Domingo, 6000 feet; Oconeque, Carabaya, 7000 feet (G. Ockenden, Mus. Druce).

This species is allied to Dicentria peruda, Druce.

## Meragisa rufipuncta, sp. n.

Male.-Head grey ; palpi black, the third joint yellowish brown; antennæ black; collar black; tegulæ grey, tipped with black ; thorax grey ; abdomen blackish brown, the base clothed with yellow hairs; the anus grey; the underside of the thorax, abdomen, and legs yellow. Primaries silvery grey, crossed by fine waved black lines and irrorated with black scales; a large reddish-brown spot close to the base, one in the cell, two near the apex, and one at the anal angle; the fringe alternately black and grey: secondaries greyish black, the base and inner margin yellow; the fringe yellow and black. Underside: primaries blackish grey, the base and outer margin from the apex to the anal angle yellow : secondaries pale yellow, clouded with dark grey beyond the middle.

Expanse $2 \frac{1}{4}$ inches.
Hab. S.E. Peru, Santo Domingo, 6000 feet (G. Ockenden, Mus. Druce).
LXI.-The Gentric Arrangement of the African Squirrels. By Uldfield Thomas.
(Published by permission of the Trustees of the British Museum.)
In the Journal of the Bombay Natural History Society for last year * I ventured to give a list of the Asiatic Squirrels,

[^63]sorted into their respective genera, in the modern restricted sense of the word, and the present paper is an attempt similarly to arrange the African species.

These latter are in a sense much more complicated and difficult than their Asiatic allies, as the groups are less obvious in general character, so that a careful study of the teeth of every species has had to be made and the animals sorted accordingly.

It proves unfortunately that a larger number of genera than is either pleasant or convenient demand recognition, if we are to uphold the sound principle enunciated by Forsyth Major that squirrels should be classified by their dental and cranial characters just as other rodents are, and do not rely on such superficial characters as the presence or absence of stripes, or similar external characters. I have tried to be as conservative as possible, but there seems no stopping-place between the present arrangement and the wholesale and inconvenient lumping of all the forms in a single genus. Such a lumping would conceal the natural relationships of the different species and ignore all the iuportant structural characters now dealt with.

The basis of this work is the classical paper of 1893 , by Dr. Forsyth Major, adopted and modified by myself in 1897 t, but now become more or less obsolete, and needing bringing up to date by the examination of the skulls and teeth of all the species known.

The following is a synopsis of the genera which appear to be recognizable :-
I. Size not minute, skull-length at least 30 mm . Skull normal ; anterior zygoma-root slanted, its anterior face looking downwards and forwards. (Sciurinæ.)
A. Fur soft, not spinous. Palate not or little produced behind molars. Postorbital processes well dereloped, directed outwards, near middle of combined orbito-temporal fossa.
a. Size small or medium ; greatest skull-length less than 62 mm . $a^{2}$. Lower molars basin-shaped as in Sciurus.
$a^{3}$. Skull normal, forehead flat. Anteorbital foramen in front of level of premolars.

$$
a^{4} \text {. Cheek-teeth } \frac{5}{4} \ddagger \ldots \ldots \ldots . . . . . . . . . . . . \text {. . . . . Sciurus. }
$$

[^64]$\dagger$ P. Z. S. 1897, p. 933.
$\ddagger$ S. persicus, with only ${ }_{4}^{4}$ cheek-teeth, but similar to true Sciurus in all other characters, should form a special subgenus, which might be called Tenes.
$b^{2}$. Lower molars more or less ridged transversely. Teeth $\frac{5}{4}$.
$c^{3}$. Lower molars regularly and deeply ridged, without high cusps. Muzzle very long .............. 4. Funisciurus.
$d^{3}$. Lower molars irregularly ridged, with high cusps. Muzzle not specially elongated
5. Paraxerus.
b. Size very large, skull-length exceeding 64 mm .; zygoma-root bowed orer as in Terus, its front edge surpassing the maxillopremaxillary suture. Cheek-teeth $\frac{4}{4}$.
$c^{2}$. Skull normal. Muzzle short; bullæ large; anteorbital foramen rounded........................ . 6. Protoxerus.
$d^{2}$. Skull elongate. Muzzle long; bullæ small; anteorbital foramen slit-like
7. Epixerus.
B. Fur spinous. Palate produced in middle line some way behind mulars. Ridge of zygoma-root strongly bowed forwards. Postorbital processes directed backwards, near the hinder end of the combined orbito-temporal fossæ.
c. Brachyodont, or very slightly hypsodunt. (Size smaller, skulllength below 53 mm .)
$e^{2}$. Cheek-teeth $\frac{5}{4}$. Skull flattened . . . . . . . . . 8. Atlantoxerus. $f^{2}$. Cheek-teeth $\frac{4}{4}$. Skull more arched ...... 9. Xerus.
d. Strongly hypsodont. (Length of skull above 55 mm .)
$g^{2}$. Cheek-teeth $\frac{4}{4}$. Skull arched, broad and heavy.
10. Geosciurus.
$h^{2}$. Cheek-teeth ${\underset{4}{4}}_{5}^{5}$. Skull high, narrow . ..... 11. Euxerus.
II. Size minute, skull-length about 65 mm . Skull highly abnormal: anterior zygomatic plate vertical; postorbital processes minute : orbits occupying practically the whole of the orbito-temporal fossa. (Nannosciurinæ.)
e. Cheek-teeth $\frac{4}{4}$. Ectopterygoid suppressed.... 12. Nyosciurus.

## 1. Sciurus.

Type.
Linn. Syst. Nat. (10) i. p. 63 (1758) . . . . . . . . . . . . . . . S. vulgaris.
Three African species, with distinctly basin-shaped lower molars and $\frac{5}{4}$ cheek-teeth, may be provisionally referred to Sciurus. They are not very uniform among themselves in their skull-shapes, nor is any one of them closely similar to S. vulgaris, but the many forms of Sciurus found in the East present so great a range of variation that no tangible or constant characters can be found to separate off these African species.

The three are S. poensis, Smith, lucifer, Thos., and muenzorii, Schwann.

It is rather a surprise to find S. poensis is not a Funisciurus, but has Sciurus-like basin-shaped molars. S. lucifer is more doubtful, and may perhaps be a Paraxerus, but no specimens with unworn teeth are as yet available.

## 2. Heliosciurus.

Trouessart, Le Nat. ii. no. 37, p. 292 (1850)
Type.
Sciurus b, a, Major, P. Z. S. 1893, p. 189.
Skull square and strongly built. Anteorbital foramen well in front of the level of the cheek-teeth. Anterior ridgre of zygoma-root strongly marked, stopping abruptly just at the maxillo-premaxillary suture.

Teeth $\frac{4}{4}$; the single premolar large, its anterior cusp very prominent and evidently taking on the function of $p^{3}$. Molars of typical Sciurus structure, the lower ones clearly basinshaped, without trace of transverse ridges.

Range. Ethiopian Region except South Africa.
List of species below.

## 3. Myrsilus.

External form normally Sciurine, but tail unusually long and slender.

Skull unusually shaped, very high, strongly convex in the naso-frontal region; maxillary masseteric fossa large, it; upper ridge extending some way past the maxillo-premaxillary suture, as in Protoxerus; anteorbital foramen large, rounded, open, its hinder edge above $p^{4}$, the part of the zygoma-root behind it reduced to a broad bar, an approach to this structure being shown by Protoxerus.

Sheek-teeth $\frac{5}{4}$.
Loweï molars rather of the irregular basin-shaped structure found in Proioxerus, not transversely ridged.

Range. W. Africa; Liberia to Ashantee.
Myrsilus is a very peculiar form whose affinities I feel by

* II. annulatus, Trouessart et suct. al., but the evidence for the identification of Desmarest's non-lonalised S. annulatus, of which the type no longer exists, with the Gambian squirrel is so insufficient that I am not prepared to accept it.
no means sure about. Probably it is most akin to Protoxerus, in which Dr. Forsyth Major included it, but the shape of its skull is so very different that there can be no doubt it should be allowed generic rank.

## 4. Funisciurus.

Trouessart, Le Nat. ii. no. 37, p. 293 (1880) ........ F. lemniscutus.
Xerus, subg. Paraxerus, Major, t. c. p. 189 (in part.; not the type).
Skull elongate, smooth, rounded above, with a long muzzle ; anterior ridge of zygoma-root falling far short of the maxillopremaxillary suture ; infraorbital foramen narrow, slit-like, in front of the level of $p^{3}$.

Cheek-teeth $\frac{5}{4}$, hypsodont, rounded in section. $P^{3}$ proportionally well developed. $P^{\star}$ without specially marked anterior cu-p. Lower molars consisting of tour well-marked transverse ridges, subequal in height, with well-define d (usually blackened) clefts between them ; no individual cusps much surpassin. the general level of the teeth. (See figures by de Winton, Aun. \& Mag. N. H. (7) ii. p. 10, 1898.)

Range. West African Subregion only *.
This genus would seem to be the representative of Paraxerus in the West African Forest region. The teeth of Funisciurus are very highly specialized, far more so than in Pararerus, and may be readily recognized by the characters above given.

## 5. Paraxerus.

Xerus, subg. Paraxerus, Major, P. Z. S. 1893, p. $189 \ldots$. ... P. cepapi.
Skull somewhat elongate and rounded, but less so than in Funisciurus, the muzzle intermediate between that of the latter and normal squirrels. Anteorbital foramen and zygomatic ridge as in Fiunisciurus.

Cheek-teeth $\frac{5}{4}$. $\quad P^{3}$ well developed ; $p^{4}$ rounded in section, without prominent anterior cusp. Molars rather hypsolont, and with a tendency to the development of the transverse ridges found in Funisciurus, but less specialized than those of the latter. Lower molars similarly with four transverse

[^65]ridges, but these are irregular in development and shape, and are considerably surpassed in height by the lateral cusps, especially that at the antero-internal corner of each tooth.

Range. Ethiopian Region, most numerous in the east and south.

> 6. Protoxerus.

Xerus, subg. Protoicerus, Major, P. Z. S. 1893, p. 189 .. P. stangeri.
Size very large. Skull heavily built, of normal shape; upper part of anturior zygoma-root bowed over as in the Spiny Squirrels (Xerus, \&c.), its ridge carried forward beyond the maxillo-premaxillary suture; anteorbital foramen rounded, often very large.

Cheek-teeth $\begin{aligned} & 4 \\ & 4\end{aligned}$, in structure somewhat intermediate between those of Terus and the true Squirrels. (Cf\%. figures by Major, l.c.)
liange. West African Forest region, eastwards into Uganda.

The six known forms of Protoxerus were worked out by me in $1906 \%$, and considered all to be subspecies of $P$. stangeri.

## 7. Epixerus.

Genus novum.
Type.
E. voilsoni
(Sciurus wilsoni, du Ch.).
General characters as in Protoxerus, but the skull elongated, with a long muzzle, as in Funisciurus. Anteorbital foramen narrow, compressed, slit-like. Bullæ comparatively very small. Palate produced behind molars further than in any of the previous genera, more approaching the Jerus group.

Cheek-teeth $\frac{4}{4}$. Lower molars simple, basin-shaped, each with four well-marked cusps at the corners.

Range. West Africa.
The two Giant Squirrels that I refer to this genus, E. wilsori and ebii, were transferred by de Winton from Major's Protoxerus to Funisciurus, a transference which I accepted in my paper on African Giant Squirrels, but I now think that, judging by the characters of the zygomatic ridge and molar structure, their resemblance to Funisciurus is merely accidental, and that they ought to constitute a group by themselves.

$$
\text { * Ann. Mag. N. H. (尔) xviii. p. } 295 \text { (1906). }
$$

## 8. Atlantoxerus.

Terus, subg. Atlentorerus, Major, P. Z. S. 1893, p. 189.. A. yetulus. Skull broal, low, and depressed; the forehead flat. Zygomata widely expanded.

Cheek-tecth ${ }^{5}, p^{3}$ well developed, standing in front of the middle of $p^{2}$, which is much smaller than $m^{2}$.

Molars brachyodont, at least as compared with those of Geosciurus and Euxerus, simple in structure.

Range. N. Africa, Morocco, \&c.

## 9. Xerus.

Sciurus, subg. Xerus, Hempr. \& Ehrenb. Symb. Phys.
Type.
i. text to pl. ix. (1832)
X. brachyotus.

Skull much more bowed than in Atlantorems, its upper profile convex. Zygomata rather less expanded.

Cheek-teeth $\underset{4}{4}, p^{4}$ little smaller than $m^{1}$.
Molars brachyodont, simple.
Range. N.E. Africa (Abyssinia, Somali, and E. Africa).

## 10. Geosciurus.

Skull large, heavy, bowed, with very thick zygomata. Postorbital processes thick, short, directed hackwards close to the hinder end of the orbito-temporal fossa.

Cheek-teeth $\frac{4}{4} ; p^{4}$ large, rounded.
Molars very heavy, hypsodont, rounded.
Range. South Africa, western half.

## 11. Euxerus.

Skull high, long, narrow; the zygomata very little expanded, in marked contrast to those of the other three gemera

[^66]of this group. Postorbital processes much reduced, directed backwards.

Check-teeth $\frac{5}{4} ; \eta^{3}$ disproportionally small as compared with the large $\gamma^{4}$, which is of nearly the same size as the molars.

Molars highly hypsodont.
liunge. West African Forest region, extending eastwards into British East Africa.

## 12. Myosciurus.

Genus novum .................................. . . M. minutus
(Sciurus minutus, de Chaillu).
Size very small, the single species not larger than a honsemouse.

Skull as in the Oriental Nannosciurus, with the exception that the ectopteryguil is aborted and the touth-row is a little further back, the lower ellge of the zygoma-ro it coming opposite the premelar instead of the anterior or midlle molar.

Cheek-teeth $\frac{4}{4}$ as against $\frac{5}{5}$ in Nannosciurus.
Molars smaller than in Nonnosciurus, but similar in structure.

Range. West Africa (Gaboon).
The absence of $\mu^{3}$, present in all the Asiatic Nennosciuri, and the suppression of the ectopterygoid, well-developed in the members of that genus, as in nearly all other squirrels, indicate that the African Pigmy Squirrel should be separated generically from its Asiatic allies.

The fullowing is a list of the African Squirrels placed in their respective genera. The species are arranged alphabetically in each genus. Forms which have been described
had not seen, but was merely quoting from Geoffror) was said to be "perhaps a species of $m y$ genus Tenotis . . . ."; and the rule ('Science," 1907, p. 52l, says distinctly ( $\epsilon . \gamma$ ) that a species which the author doubtfully refers to his geuus caunut be taken as the trpe of it. Nor can Tentis be taken as a monotypic genus (rule c), though " T. griseus" is the only species mentioned, fur the genus is distinctly formed fur "atl the squirrels with pouches....": so that all the pouched squirrels knuwn in $1: 17$ woud have been includel in it, and it would have been equally ralid had the doubtfully inclubed $T$. grisens not been mentioned.
swondly, the deriaite quotation of Teme'ts as a syonym of Tamias by
 to bear the authority of a "fir-t reviser," and so to settle the question.

I fail to see any reason why Geoffing's obrious misprint of "erythornus" should not be corrected into erythropis.
as subspecios are not included, unless there is a probability of their deserving specific rank:-

1. Sciurus, Linn.
lucifer, Thos.
poensis, A. Smith.
suwenzorii, Schw.
2. Heliosciurus, Trouess.
abassensis, Neum.
bongensis, Heuyl.
grambianus, $O g$. ( $=$ annulatus, auct.)
isabellinus, $\mathrm{G}_{7}$. kaffensis, Neum. kenir, Neum. multicolor, Rüpp. mutabilis, Pet. punctatus, Temm. rufobrachiatus, Waterh. undulatus, True.
3. Myrsilus, Thob.
aubinni, Gray. salæ, Jent.
4. Funisciurus, Trouess.
akka, de Wint.
anerythrus, Thos.
auriculatus, Matsch.
carruthersi, Thos. congicus, Kuhl. erythrogenys, Waterh. isabella, Gray. lemniscatus, Le C. leucostigma, Temm. mandingo, Thos. mystax, de Wint. pembertoni, Thos. pyrrhopus, F. Cue. raptorum, Thos. substriatus, de Wint.
5. Paraxerus, $M a j$ 。
alexandri, Tloos. \& $\mathrm{Tr}^{2}$.
antonix, Thos. \&. Wr.
aruscensis, Pag.
boehmi, Reich.
cepapi, A. Smith.
emini, Stuhlm.
ganana, Rhoads.
jacksoni, de Wint. ochraceus, Huet. palliatus, Pet. pauli, Matsch. sponsus, Thos. \& $W_{r}$. yulei, Thes.
6. Protoxerus, Maj. stangeri, Waterk. (with five subspecies).
7. Epixerus, Thos.
ebii, Temm.
wilsoni, $d u$ Chaillu.
8. Atlantoxerus, Maj. getulus, Linn.
9. Xerus, Hempr. \& Ehr.
brachyotus, $H, \& E$. rutilus, Cretzschm.
10. Geosciurus, $A$. Sm. capensis, Kerr.
11. Euxorus, Thoe,
erythropus, Geoff. microdon, Thos.
12. Myosciurus, Thos. minutus, du Chaillu.

Owing to want of skulls I am unable definitely to place :-
favivittis, Peters, whose external appearance is that of Funisciurus congicus, but whose geographical position and shape of skull (as figured by Peters) suggest Paraxerus.
buyonii, Bocage, probably related to Sciurus puensis, but Funisciurus substrintus has a similar iodistinct lateral band, and perhapsa real relationship to it.
LXII. - Remarles on some Genera of the Scoliidæ, with Mescriptions of New Species. By Rowland E. Turner, F.Z.S., F.E.S.

Genus Iswara, Westw.

Isuara, W'estw. Trans. Ent. Soc. Londen, (2) i. 7, p. 232 (1851), ${ }^{\circ}$. Myzine, Radosz. Hore Soc. Ent. Ross. xx. p. 40 (1886), ${ }^{3}$.
Komarowia, Radosz. l. c. p. 41, 오.
Milluta, A ndré, Bull. Soc. Ent. Fr. p. 143 (1898), ठ.
Mayrettina, Ashm. Proc. Ent. Soc. Washington, iv. p. 144 (1901), ${ }^{\text {z. }}$
There is considerable variation in different species of this genus in the neuration, especially in the shape of the second cubital cell, which is sometimes pointed on the radial nervure as in typical Milluta, but longer than the third in I. tartara, Sauss. There seem, however, to be so many intermediate forms that I cannot regard the character of generic importance. The radial cell also varies in length and is more or less truncated at the extremity; Ashmead says that it is lanceolate in nocturna, Mor., but in the original description Morawitz distinctly says "die Spitze mehr oder weniger deutlich abgestutat." The antennæ also vary much in length, but this might be expected in insects which have become adapted to nocturnal habits. I have not seen specimens of Milluta chobauti, André, or of Magrettina nocturna, Mor., the species given as typical of those genera; but a specimen in the British Museum from Ormarah, Baluchistan, corresponds well with Andee's description in most respects, the intermediate coxæare, however, narrowly separated. Radoskowsky gives good plates of the male genitalia, which differ much from typical Myzine, but do not seem to show any affinity to Methoca. The only female I have seen, Komarouia victoriosa, Radosz. $=I$. tartura, Sauss., seems to me to show conclusively that the genus is nearest to Myzine. Much more material is required for a thorough study of the genus, but until this is available it is better to abstain from any attempt at generic subdivision. Mons. André has probably overlooked Iswara owing to Westwood's mistake in placing it in the Thynnidæ. I agree with him in treatiog thie distinctions given by Ashmead for Magretiina as specific and not generic ; but I camot consider the genus correctly placed in the Mutillidx.

## Myzine clavicornis, sp. n.

t. Clypeus short, very minutely punctured, convex, and lonuitudinally subcarinate at the base, the apical margin
trmeate, a smooth obliquely depressed triangular truncation from the centre to the apex. Head closely and rather finely punctured, most closely on the front; the inter-antennal prominence absent, only represented by a small tubercle on each side above the base of the antenna ; cyes widely and rather deeply emarginate ; the ocelli small, the posterior pair rather nearer to the eyes than to each other. Antemm as long as the thorax and median segment combined; the scape shining, very sparsely punctured beneath and uo longer than the third joint of the flagellum; the joints of the flagellum gradually increasing in thickness to the apex, the apical joint nearly twice as thick as the basal. Thorax deeply but sparsely punctured, the mesopleuræ more coarsely punctured; pronotum a little shorter than the mesonotum, consid rably nariowed anteriorly; scutellum large and subtriangular, very narrowly truncate at the apex. Median segment a little shorter than the scutellum, almost vertically truncate at the apex, more closely punctured, with a longitudinal depression in the middle, the sides rugose. Abdomen slender, tapering slightly at the extremities, about one quarter longer than the head, thorax, and median segment combined; the basal segment smooth and shining, depressed anteriorly, with a short petiole; the other segments deeply but sparsely punctured, broader than long; the seventh dorsal segment deeply and uarrowly emarginate at the apex for the reception of the long recurved aculeus; the ventral segments shining, with a few fine scattered punctures. Radial cell more than two and a half times as long as its greatest breadth, extending for about two-fifths of its length beyond the third cubital cell ; the stigma a little more than half as long as the radial cell on the costa. Second cubital cell rinomboidal, more than twice as long on the cubital as on the radial nervure, the third cubital cell twice as long as the second on the radial, and more than half as long again on the cubital nervure; the two recurrent nevvues received slightly beyond the middle of the second and third cubital cells.

Black, with sparse white pubescence; the mandibles (except at the apex), a triangular mark at the apex of the clypeus, a minute spot above the base of each antema, the pronotum with a large blark mark reaching from the anterio: margin to beyond thie middle, the tegula, a broad transverse band at the apex of dorsal abdominal segments 1-6 slightly sinuate anteriorly on the first segment, the tibiæ, tarsi, and the apex of the femora yellow; the first dursal abdominal segment and the second more obscurely, ferruginous. Wings
hyaline, nerrures colourless, the stigma and costa pale lutaceous.

Length 7, exp. al. 10 mm .
Hab. Deesa, N.W. India (Nurse). October. Type in coll. Nurse.
The antemne are proportionally shorter and much mors strongly clayate than in other species of Dyzine.

## Myzine subpetiolata, Cam.

Plesia sulpretiolutus, Cam. Journ. Bombay Nat. Hist. Soc. xviii. n 1 Brin (1907), శో.
?. Mandibles falcate, acute at the aper. Ifead smontla and shining, sparscly punctured on the front; the clypeus, slightly produced and truncate at the apex; the antenme as long as the thoraw without the melian segment, the scape smooth and shining on the inner side, punctured and with long seta on the outer side, the first joint of the flagellum concealed, the second distinctly shorter than the third; the bead subrectangular, slight!y rounded at the posterior angles, a little broader than long and siightly convex; the ocelli in a triangle on the vertes, the postrior pair more than half as far again from each other as from the anterior, and nearly twice as far from the eyes as from each other. Thorax ond median segment shining, with a few scattered setigerous functures, the pleure very sparsely punctured; a few fine oblique strix on the sides of the median segment near the base; the pronotum one-third broader posterionly than anteriorly, as long as the breadth on the anterior marin and narrower than the head; mesonotum short, the scatellum a little shorter than the median segment. Ablomen as long as the head, thoras, and median segment combined, smooth and shining, with a few scattered hairs on the sides and on the apical margins of the rentral segments, the apical segment triangular. The second culital cell is almost as long on the culsital nervure as the first, and extemels along the transverse cabital nervure for rather less than half its length.

Fernginous red; the apex of the mandibles, eves, ocelli, and the dorsal abdominal segments black; the ventral sigments of the abdomen, apes of the prgidium, mesosternum, and femora fusco-ferriginous; a large spot on each side of the second and third audominal sermente, and a smaller che on the fourth creamy white, Wrings hyaline, nervures fusco-ferruginous.

Length 9 , exp. 12 mm .

## Hab. Quetta (Nurse). May.

This species and Plesico baluchistanensis, Cam., are undoubtedly incorrectly placed in Plesia. The male of the present species seems to be near Meria ciliata, Mor., which is only known to me by description, but subpetiolata is much more strongly punctured.

## Myzine baluchistanensis, Cam.

Plesica buthechistanensis. Cam. Journ. Bombay Nat. Hist. Soc. xviii. (1907), ơ.
q. Head nearly half as broad again as long, almost rectangular, smooth and shining, with a few punctures above the base of the antemne; the clypeus advanced and rather broadly truncate at the apex. Scape above clothed with long fulvous hairs, the second joint of the flagellum scarcely longer than the first or third. A fringe of long pale fulvous pubescence on the posterior margin of the head. Pronotum smooth and shining, with a few scattered punctures near the anterior margin, much broader than long, and very little narrowed anteriorly; propleuræ sparsely punctured, with long, thin, greyish pubescence. Mesonotum and scutellum shining, the latter with a few large punctures near the apex, the mesopleure punctured and clothed with long greyish pubescence; a small round depression on each side near the Lase of the scutellum covered with very short greyish pubescence. Median segment shining, with a deep longitudinal sulcus. Abdomen shining, very sparsely and shallowly punctured, with sparse greyish pubescence on the sides. The second cubital cell extends along the transverse cubital nervure for less than one-third the length of that nervure.

Black; the abdomen bright ferruginous; mandibles and tarsi ferruginous; calcaria whitish; tegulæ testaceous; an obscure creamy spot, obsolete in some specimens, on each side of the second and third abdominal segments. Wings pale fulvo-hyaline, nervures fuscous, the stigma almost black.

Length 9 mm .
Hab. S.W. Persia (Escalera) ; Quetta (Nurse).

## Precilotiphia albomaculata, Cam.

Pocilotiphict allomuculutu, C'am. Juurn. Bumbay ANat. IIist. Soc. xir. p. 274 (1902), ठ゙.

A specimen sent by Colonel Nurse has three cubital cells
insteal of two, as in the type. Culonel Nurse remarks: "It should therefore stand as Myzine albomaculata, Cam., and the genus Precilutiplia, founded on an abormal specimen, must lie suppressed." The same insect has been described by Nurse as the male of Myzine apimacula, Cam., which has the neuration of Plesia, and although this association of the sexes is not quite certain, it does not seem improhalle; though the male differs from other oriental species of Plusia in the short petiole and the deep slit in the apical domsal segment. The female upimaculu differs from most species of Plesia in the very feeble development of the sculpture of the apical dorsal segment, agreeing in this with the peculiar female, $P$. tricolor, Sm. The latter species may prove to be the female of Myzine dimidiaticornis, Bingh., which agrees with $!$ lesia in the almost complete absence of the slit for the reception of the aculeus on the seventh dorsal segment, which is present in all true Myzine known to me. Dinitiaticomis agrees with tricolor in the length of the second cubital cell, the elongate head, and the colour of the antemia. Specimens of $P$. tricolor from $A$ :sam have the head distinctly longer in proportion than the typical Bornco form. I fully agree with Nurse in sinking Pœcilotiphia.

## Plesia nursei, sp. n.

ő. Clypeus slightly produced and very narrowly truncate at the apex, almost smooth, thinly covered with short white pubescence. Antennæ stout, as long as the head, thorax, and median segment combined; the scape closely and rather finely punctured, shorter than the third joint of the flagellum. Interantennal prominence bilobed, covering the base of the scape. Head closely and deeply punctured, more shallowly on the vertex than on the front, with sparse white pubescence, the eyes widely but not deeply emarginate. Thomax rather sparscly punctured; the pronotum nearly as long as the mesonotum, less than twice as broad as the length in the middle, narrower than the head, the anterior margin straight with slightly prominent angles. Median segment puncturedrugose, rounded, much longer than the breadth at the base. Abdomen elongate, slender, petiolate, the first segment as long as the second and third combined, the basal third of the segment very narrow and flattened, the apical twe-thirds nodose, constricted at the extreme apex; all the segments shining and very sparsely punctured, the seventh dorsal segment not emarginate at the apex.

Black; the mandibles (except at the extreme apex), the
clypens, the apex of the interantennal prominence, a very narrow transerse band at the aper of abdominal segments $2-5$, broadly interiupted on the second segment, the anterior cose bencath, the apex of the mesosternum between the intermediate coxæ, the apex of the anterior femora, the anterior and intermediate tarsi and the tibia above, the base of the posterior tibire and the basal joint of the posterior tarsi pale yellow. Tegulæ yellow at the base. Wings hyaline, nervures black.

Length 13-14 mm.
Hab. Simla (Nurse). September.
Described from two specimens.
Near P. mandalensis, Magr., but the head is rather more coarsely punctured, the angles of the pronotum are morc prominent and the first abdominal segment much longer. Also very mear $l$ '. eitense, Turin, from Burma, but that species has a carima on the clypeits and the pronotum narrowed anteriorly; the third cubital cell in the present species and in mandulensis is only slightly longer than the second on the radial nervure, whereas in ectence it is nearly half as long again.

## Plesia (Mesa) asmarensis, sp. $\mathrm{n}_{\alpha}$

$\delta^{2}$. Clypeus broad, very slightly produced, punctured and clothed with grey pubescence, the anterior margin subtruncate. Antemæ rather slender, as long as the head, thoras, and median segment combined. Head small, coasely and closely pronctured, the interantenmal prominence raisel into an oblique carina on each side above the base of the antemm; the eyes broadly emarginate on the inner margin. Thorax shining, more finely and sparsely panctured; the pronotums narrower than the head, the auterior angles prominent; mesopleure and median segment coarsely punctured rugose; the median segment rounded, longer than the breadth at the base, and narrowed to the apex. Abdomen very slender, half as long again as the head, thorax, and median segment combined; the basal segment as long as the second and third combined, very slender, very narrow at the base, the apical two-thirds swollen and clavate, constricted at the apex, where the breadth is not more than one-fifth of the length of the segment; second segment longer than the third, gradually broadened to the apex, narrower than the third segment. All the segments shining, very minutely punctured, the seventh dorsal segment narrow, with a few large punctues near the apex, and a distinct, median, longitudinal
carina, the apex scarcely emarginato. The second and third cubital cells are about equal in length on the radial nervure ; the first recurrent nervure is received just beyond the midtle of the second cubital cell, the second at one-quarter from the base of the third cubital cell. The basal joint of the posterior tarsi is nearly equal in length to the second and third joints combined.

Black; a small spot at the apex of the clypus, a small spot on each side at the apes of the second to fitth abolominal segments, continued in a very narrow band, interrupted in the middle, on the apical margin of the fourth and fifth serments, the anterinr tibia and tarsi above, the basal joint of the intermediate tarsi and the spines of the tibite yellowish white. Wings hyaline, siightly iridescent, nervures black.

Length 10, exp. 14 mm .
Ilab. Asmara, Erythrea (purchased from II. Rotle).
'This is not a Myzine, but the male of a Plesia, and seems to be nearest to clavata, Sauss., from the Transvaal. The almost total alsence of a deep slit in the seventli dorsal segment to receive the recurved aculeus of the hypppygium is noticcahle in this group as in most of the Orieatal species of Plesia.

## Tiphia rufofemorata, Sm.

Tijhen rufofemorata, Sm. Cat. IIrm. B. M1. iii. p. 83 (18.55), 오.
Tiphiar cussiope, Cam. Mem. Manchester Phil. Soc. xli. p. 46 (1896), of.
Described by Smith from Northern India. I have seen specimens from Simla (coll. Nurse) and Masuri, all much smaller than the type.

Length 6-12 mm.

## Anthobosca moderata, sp. n.

J. Clypens short, not advanced, and very broadly truncate on the apical margin; minutely punctured, with a short, delicate, longitudinal carina which does not extend either to the base or the apex, thinly clothed with grey pubescence. Ilead rounded, finely and closely punctured, sparsely clothed with long grey pubescence; the antemme inserted rather nearer to the eyes than to each other, shorter than the thorax and median segment combined, stout, slightly tapering to the apex and very finely pubescent; the third joint of the flagellum longer than the second. Posterior ocelli further from the eves than from each other. Thorax and me lian segment very firely and closely punctured, opaque, the propleura shining and more sparsely punctured, the pronotum
tery little narrowed anteriorly; scutellum more than lale as long as the imesonotum and rounded at the apex ; median segment nearly three times as broad as long, obliquely sloped posteriorly. Abdomen fincly shagreend, fusifurm, as long as the head and thorax combined. Second abseissa of the radius half as long again as the first and fully half as long as the third; the first recurrent nervure received junt before the middle of the second culital cell, the second just before the middle of the third cubital cell. The cubital nervure of the hind wing originates at the apex of the submedian cell.

Black; clypeus, posterior margin of the pronotum, a spot on the posterior margin of the mesonotum, a large spot on the postscutellum, the base of the tegule, two spits on each side at the apex of the melian segment, a spot on each side of each of the five basal abdominal segments, the base of the seventh segment, the aj ex of the anterior femora, the anterior tibire above, the base of the interme liate and posterior femora, and the basal joints of all the tarsi yellowish white. Wings hyaline, the anterior pair with a daint fuscous tint, nervores black. The division of the first culital cell is indicated by a colourless scar.
Length 12 , exp. 17 mm .
Hab. Townsville, Q.

## Anthobosca favicornis, Sauss.

Cosila flaricormis, Sauss., Grandidier, Hist. Madagascar, xx. p. 238 (1892), 9.

Hab. Victoria (C. French) ; Tasmania; Cairns, Q.
The specimen from Victoria scems to be typical; that from Tasmania has the scape and all the tiblize and tars: fulvous; that from Cairns whilst differing little in colour from the typical form has the second abscissa of the radius fully as loing as the first, whereas the two sonthem specimens have it distinctly shorter. The wings are darker in the Victorian specimen than in the others.

As there is a gord deal of confusion in connection with some of the Fablician species of Tiphia and Senlia in the Banksian collection, a list of them with remarks may be useful.

## Genus Tiphia, Fabr.

1. T'. femorata, Fabr.--The well known European species.
2. T. quinquecincta, Fahr.-Type in Banksian collection. This is
a female of the common North-American Plesia suisequently described by Fabricius as Tiphire nomere, which name must sink. The locality given by Fabricius is of course crroneous.
3. T. varirgatu, Falr.-Type in Panksian collection. This is the European Palarus flaviper, Fabr., described by Fabricius ns Crabro flavipes. Buth mames appeared in the same work, but varieguta has priority. The species must therefore stand as $P^{\prime}$ alarus variegata, Fahr. The type has the scutellum and postscutellum yellow.
4. T. hermorthoilutis, Fabr.-The specimen in the Banksian collectiom, not the type, agrees with the short description, hut is a Stizus which I identify with little doubt as S. chrysorrhoeus, Handl.
5. T. radula, Eabr.-Type in Banksian collection. A common Australian species, now known as Dielis radula.
6. T. collaris, Fabr.-The specimen in the Banksian collection is marked, probably erroneously, as the trpe. It is the Oriental species now known as Diclis fimbriata, Burm.
7. T. pelestris, Fabr.-Type in Banksian collection, without the abdomen. A female Thynnus of the typical group. It seems to be still unique.

## Genus Scolita.

1. S. nigrita, Fabr.-Type in Banksian collection. A common African species.
2. S. quadrimaculata, Fabr.-Preriously figured by Drury as Tespua maculata.
3. S. septemcincla, Fabr.-Type in Banksian collection. A common Australian species. I have no hesitation in sinking the name, considering it to be the male of Dielis ratula, Fabr.
4. S. flarifrons, Fabr.-A common South European species.
5. S. ferruginea, Fabr.-Type in Banksian collection. Locality, Cooktown, Queensland.
f. S. quinquefasciata, Fabr.-Type in Banksian collection. I am not sure that this is the same insect described by Saussure under the name, the description being too short for certainty.
6. S. ratela, Fabr.-Previously figured by Drury as Sphex plumipes.
7. S. morio, Fabr.-Type in Banksian collection. This is a female of the species now standing in the British Museum collection as Scolia cyanea, Lep.
8. S. bicincta, Fabr.-Type in Banksian collection. A common North American species.
9. S. verticalis, Fabr.--Typo in Banksian collection. I have been unable to find specimens of this male in recent Australian collections.
10. S. quadripustulata, Fabr.-Type in Banksian collection. A common Oriental species.
11. S. quadripunctatu, Fabr.-A well-known species.
12. S. sexincta, Fabr.-The specimen in the Banksian collection, not the type, is the male of Plesia quinquecincta, Fabr. (Tiphia q.). Whether it is identical with the type I cannot say.

## Family Mutillidæ.

## Subfamily Myrarosines.

## Typhoctes guatemalensis, sp. n.

¢. Head subquadrate, a little broader than long, broader thin the pronotum, punctured elosely, the punctures tending to become confluent longitudinaily, very thinly clothed with black pubescence; eyes extending rather nearer to the base of the mandibles than to the posterior margin of the head, elongate ovate ; ocelli absent. Antemnæ filiform, nearly as Jong as the thorax, the second joint of the fiagellum half as long again as the first and a little longer than the third, the apical joints slender but short. Pronotum a little narrower than the head, as broad as the metanotum, from which it is separated by a deep transversa suture; longitudinally striated and sparsely clothed with long greyish pubescence. Pleuræ finely horizontally striate. Metanotum longer than the pronotum, longer than broad, obliquely sloped posteriorly, not truncate, longitudinally striated in the middle and at the base, obscurely punctured at the sides and apex. Abdomen shining, very finely and closely punctured, very sparsely clothed with long cinereous pubescence on the sides and apex, a transverse band of short whitish pubescence at the apex of each segment; first segment triangular, attached to the thorax by a short petiole, the second segment large, twice as long as the third, with a strong constriction between the first and second segments. Intermediate tibiæ with two apical spines.

Black; the two basal joints of the flagellum testaceous ; the metathorax (except a large black spot at the base), the first abdominal segment (except a triangular black spot at the apex), the basc of the posterior tibix, and the intermediate and posterior trochanters and coxæ ferruginous; calcaria white.

Length 7 mm .

Huh. San Geronimo, Guatemala (Champion).
Type in B. M., ex coll. Godman-Salvin.
I plase this species in Typhoctes with some doulst, not having ssen a typical female of the genus. It appearz, however, to approach more nearly to that genus than to Myrmosa, especially in the shape of the first abluminal segment and the complete absence of ocelli.

> LAIII.-Two new Mutillila from Qucensland.
> By the late Lieut.-Col. C. 'T. Bingmar.

Mutilla (Ephutomorpha ?) doddi, sp. n.
6. Antemme dark castancous brown almost hlack, slightly paler at their apices; clypens, cheeks, face in front, and head alonve coverel with lonig dense ghllun yellow pile, beneath anl the space behind the eyes with short black scattered hairs; pro- anl mesonotam, the tegule, scutellum, postscutellum, median segment, and ablomen dark castancous hrown coverel with short erect hairs, black on the thorax, white on the median sesment and 1 st ahblominal segment; on the 2nd and following segments the hairs are black with a tuft of long snow-white hairs laterally at base and apex of the 2 nd and at the bases of the 3 rd and 4 th segments, apices alon of the 3nt and following segments with a broad band of white hairs medially. Wing: dark fuscous brown with little or no iridescent gloss, their bases up to the discoidal cell in the fore and to apex of median cell in the hind wing hyaline; the fore wing with one recurrent nervure only. Legs black with black pile, the intermediate and posterior legs with the femora above except at apex and the lst jnint of the tarsi at base with long white hairs. Head small, narrow, much narrower than the thorax; mandibles simple, acute; eyes round, very convex ; antennæ minutely punctured, opaque; thorax densely and somewhat coarsely punctured, the prothorax dentate antero-laterally; mesonotum convex, with a deep, smooth, short, transverse sulcus between it and the scutellum, the latter conical, raisel, rounded above; median segment depressed, very coarsely cribrate, the sides produced posteriorly into short triaugular laminæ; abdomen finely and closely punctured.

Length, उ, 17 ; Exp. 32 mm .
Hab. Queensland, North Australia.

This very beautiful insect was collected by Mr. F. P. Dold at 'Townsville in Queensland. It is a remarkable form, combining the characters of two genera as given by Mons. Eruest André in IVytsman's 'Genera Insectorum,' 11 L'asc. Mutillidæ. With the eyes of the genus Fphutomorphee, André, round, entire, and prominently convex, it has tha dentate median segment proper only to Odontomutilla, Ashmead. The of is unknown. 'I'ype in British Museum.

## Ephutomorpha aurigera, sp. n.

q. Antennæ pale reddish yellow, infuscate towards apex, the terminal three or four joints black; head dark red; thorax and legs reldish yellow ; abdomen metallic purple, with a coppery sheen in centin light; ; thorax above sparsely, abdomen more densely clothed with bright metallic golden pile; on the abdomen this is restricted to a broad longiturlimal band down the middle, narrowing posteriorly and changing abruptly on the apical three segments to silvery. Inead, thorax, legs, and abdomen very sparsely covere also with long erect black hairs. Head transverse, slightly broader than the thorax; eyes very conves, round and prominent ; thorax elongate, subrectangular, narowed somewhat posteriorly ; abdomen sessile; head and thorax somewhat coarsely, abdomen more finely punctured.

Length $5 \frac{1}{2} \mathrm{~mm}$.
Hab. Queensland, N.E. Australia.
Taken by Mr. F. P. Dodd. 'Type in British Museum.

## LXIV.-Four new Tabanus Species from India and Assam. By Gertrude Ricardo.

THE descriptions of these four Tabanus species are now published at the request of Mr. F. M. Howlett, of the Agricultural Research Institute, Pusa, Bengal, as he needs the names for use in a report being prepared in India. They will be incorporated shortly in a paper on all the Tabanus species of the Oriental Region. The types are all preserved in the British Museum Collection.

## Tabanus likasiensis, ㅇ, sp. n.

Type ( 8 ) and two other females from Khasi Hills, Assam, 1000-3000 ft., in Brit. Mus. Coll. One female from Meernt in Calcutta Coll.

A black medium-sized species, with white bands on the ahdomen. Antennæ, palpi, and legs blackish. Wings hyaline, tinged with brown.

Length $15-16 \mathrm{~mm}$.
Nearly allied to Tabanus justorius, Rondani, from Borneo, but distinguished by the more hyaline wings, the forehead parallel, and the palpi darker.

Face covered with greyish tomentum in the middle, on the cheeks and subcallus with yellowish-brown tromentum, the pubescence black. Beard black. Pulpion ontside appearing blackish, covered with grey tomentum and with black pubescence, on the inside obscure reddishy yellow, long and pointed, stouter at the base. Antenne dull reddish black or black, the first two joints with grey tomentum and black pubescence, the tonth of the third joint small. Forehead same colour as subcallus, the same width throughout, with a few black hairs, nearly sevon times as long as it is broad; the frontal callus oblong, narrow, brown, not reaching the eyes, furrowed in the middle, with a long, narrow, linear extension. Thorax, scutellum, and ablomen brownish black, the former with grey tomentum and traces of two stripes, a tuft of white hairs behind the base of wings; breast black, with grey tomentum and black and white hairs. Scutellum on outer border covered with grey tomentum, pubescence black, white on the outer grey border. Abdomen with distinct white-haired lands on every segment except the seventh, enlarging slightly in the middle to half-moon spots and wider at the sides; underside similar. Legs black or brownish black, with black pubescence; coxæ with white pubescence and a few white hairs on hind femora below; the tibix are sometimes olbscurely reddish brown at base. Wings clear, tinged faintly with brown; in one specimen it is more distinct and borders the longitudinal veins.

## Tabanus leucohirtus, ㅇ, sp. n.

Type ( $\circ$ ) and two others from Kanara, Bombay, sent fur identification by Mr. F. MI. Howlett.

A medium-sized dull reddish-brown species, not unlike Takamus fumifer, Walker, in appearance, but distinguished from it by the absence of spots on the ablomen and by the dark beard and hairs on face. Wings tinged with brown. Legs blackish brown; tibiæ obscurely red.

Length $20-22 \mathrm{~mm}$.
Face covesed with grey tomentum, pubescence brown, but some white lairs are visible on the sides of face; beard is
similar, but very scanty. Palpi dull reddish, thickly covered with black hairs, large, stout, ending in an obtuse point. Subcallus, forehead, and sides of checks covered with yellowish-brown tomentum. Antennce bright reddish, the apex black; the first two joints with black pubescence; the third joint long and slender, the tooth near the base distinct, crowned with a few black hairs. Forehead narrow, about seven times as long as it is narrow, very slightly narrower anteriorly; the frontal callus dark reddish brown, narrow, oblong, not reaching the eyes, prolonged as a narrow raised line towards the vertex; hairs on forehead black. Thorax brown, with yellowish-brown tomentum and scattered black pubescence; a few appressed pale yellow hairs are visible chiefly on the anterior half of dorsum and at sides. Scutellum similar. Abdomen dull reddish, appearing darker owing to the dense short pubescence; segmentations obscurely yellowish or lighter, a few white hairs at the sides of abdomen; underside brown, but with grey tomentum on the sides and the segmentations, which latter are wider and more distinct ; the pubescence black. Legs with black pubescence, but the fore coxæ with long white pubescence ; the fore tibir reddish at base, the others reddish brown. Wings with brown veins and stigma, tinged with brown on the fure border, becoming paler on the posterior border.

Tabanus bicallosus, ठo ㅇ, sp. n.
Type ( $\begin{gathered}\text { ) from Pusa, Bengal. }\end{gathered}$
Type ( $~$ ) and three other females from the same place.
These specimens were sent to me for identification by Mr. F. M. Howlett from India.

This small species might at first sight be taken for a small specimen of T'abanus striatus, Fabr., but is at once distinguished from it by the two separate calli of the forehead. It is very nearly allied to Tabanus gratus, Loew, which is distributed over South, Central, and West Africa, reaching up to Egypt, as I had a specimen sent me from the Suez Canal. The wholly yellow legs, narrower median stripe of abdomen the same width throughout (in the African species it is wider on the third and fourth segments), and the prolongation of the thoracic stripes on to the scutellum seem the only differences between the Indian and the African specimens.

Black, with five grey stripes on the thorax and three on the abdomen. Legs and antennæ yellowish. Wings clear.

Length 10 mm .
Ann. \& Mag. N. Hist. Ser. 8. Vol. iii.
of.-Face covered with grey tomentum and with white pubescence. Beard white. Palpi greyish, with some white hairs at base, and black hairs elsewhere, but these last are not very numerous.
Antennce: the first joint yellow, the second and third red, tooth at base small. Foreliced broad, quite a third narrower anteriorly, and four times as long as it is wide, covered with yellowish-brown tomentum and with some black pubescence; the frontal callus yellowish brown, nearly square, and almost reaching the eyes; beyond it and sometimes connected by a very fine line is an irregular-shaped black or brownish callus isolated in the middle of the forehead. Eyes with three eross-bands. Thorax: the median stripe is linear, the other ones broad, sides of thoras greyish, with black pubescence. Scutellum: the lateral stripes are continued here, leaving the centre blackish. Abdomen narrow, all three stripes reaching from the first to the sixth segment; sides grey, with white pubescence; underside covered with grey tomentum. Legs uniformly reddish yellow, only the tarsi a little darker; the fenora with grey tomentum and white pubescence. Wings clear, the stigma and veins yellow.

ठ. -The male is identical. Eyes with large facets above; the small ones on the lower third of cyes are continued round the head as a very narrow border.

Tabanus nemocallosus, $\ddagger$, sp. n.
Type ( $\circ$ ) and another female from Pusa, Bengal, sent to me for identification by Mr. F. M. Howlett.

A medium-sized species, distinguished by the rather broad forehead, not natrower anteriorly, with no callus or spots. Abdomen blackish brown, marked with greyish-yellow median and lateral spots.

Length 13 mm .
Face and forehead covered with greyish tomentum, the former with white pubescence. Beard scanty, white. Palpi yellowish white, with white pubescence, stout, ending in a short point. Antrnnce reddish yellow, the first two joints pale yellow, the third with hardly any tooth. Thorax, scutellum, and abdomen blackish brown, the former with five distinct greyish-yellow stripes; the dorsum with some grey tomentum and with appressed pale fulvous pubescence; scutellum with the same and with grey tomentum. Abdomen with an almost continuous median stripe formed of grey, tomentose, narrow, triangular spots, and with irregularshaped, roundish, grey, tomentose spots on the siles, the
pubescence on these short, pale fulvous; some black pubescence on the dark parts of the dorsum, the sides of the first two or three segments pale reddish; underside lighter, covered with grey tomentum. Legs pale yellowish red, the tarsi brown ; the pubescence white on femora and tibiæ, black on the tarsi. Wings hyaline, with brown veins and yellow stigma; a long appendix on branch of the third vein.

> LXV.-Oriental Rhynchotn Heteroptera. By W. L. Distant.

Figures of the genera here proposed and of most of the new species will appear in the Appendix to the Rhynchotal portion of the 'Fauna of British India,' now in preparation.

## Fam. Lygæidæ.

## Dinomachus indicus, sp. n.

Head greyish brown, pilose, with some darker spots near base; pronotum brownish ochraccous, darkly punctate, transversely impressed before middle, the auterior area or lobe discally dark castaneous, the margins narrowly ochraceous ; scutellum brownish ochraccous, darkly punctate, with a central longitudinal line (not reaching base) and the apex pale ochraceous; corium pale dull ochraccous, longitudinally punctate, the apical angles castaneous; membrane subhyaline, the veins a little darker ; body beneath thickly greyishly pilose (imperfectly scen in carded typical specimen); legs brownish ochraceous, posterior tibiæ with three broad dark annulations; antennæ greyish brown, first joint slightly passing apex of head, second joint a little longer than third (fourth mutilated in typical specimen) ; pronotum with the lateral margins strongly sinuate, the posterior margin concavely sinuate before scutellum, the posterior area or lobe much more strongly punctate than the anterior area, the pale narrow margins impunctate; legs somewhat longly pilose ; rostrum imperfectly seen in carded typical specimen.

Length $6 \frac{1}{2} \mathrm{~mm}$.
Hab. "India" (Vienna Museum).

> Pamera emersoni, sp. n.

Head and anterios lobe of pronotum black, posterior
pronotal lobe more purplish black, with an ochraccous submarginal line near each lateral angle; scutellum black; corium ochraceous with dark punctures, inner margin and apex of clavus, inner marginal area and apical margin of corium black; membrane fuscous brown, with curved longitudinal whitish lines; body beneath, legs, and rostrum black; second joint of rostrum, apices of anterior femora, apical halves of intermediate femora, and anterior and intermediate tiljiæ and tarsi, ochraceous, the latter infuscate at apices; (posterior legs mutilated in trpical specimen ;) antennæ black, the apical joint with its hasal half stramineous, first joint slightly passing apex of head, sceond and fourth joints subequal in length, each a little longer than third; pronotal collar broad, anterior pronotal lobe about one and a half times as long as posterior lobe and very distinctly narrower ; corium with the dark punctures in longitudinal series; anterior femora fincly but prominently spined beneath; rostrum reaching the anterior coxæ.

## Length 5 mm .

Hab. Ceylon (Vienna Museum).
Adauctus, gen. nov.
Suborate; head about as long as broad, subtriangular, obliquely narrowed anteriorly, the central lobe prominent; ocelli near base and close to eres; antenuæ with the basal joint slightly passing apex of head, second joint a little longest; rostrum reaching the intermediate coxæ, basal joint not reaching base of head, second joint extending to anterior coxæ; pronotum not transsersely constricted, the lateral margins strongly carinate, and anteriorly moderately rounded and narrowed, posterior margin truncate ; scutellum a little longer than broad, the lateral margins obliquely straight: corium apically strongly broadened, the apical masegin wide, obliquely straight, claval ridges prominent; membuane slightly passing abdominal apex (veins to both corium and membrane will be shown in figure) ; anterior femora thiskened, finely spined beneath, tibiæ somewhat longly spinulose ; sternum coarsely punctate, the prosternum more finely pu-nctate.

In the cummeration of the Oriental Lygieidr to be placed near Diniella and Microcoris.

Adiructus cupreus, sp. n.
Head, pronotum, ana scutellum pale cupreous; lateral margins of the pronotum (not extending to the lateral
angles) pale ochraccous; corium stramincous; two small spots in clarus, three on outer margin of claval suture, one beyond middle of costal margin, a large transierse spot at apical angle, and a linear spot near middle of apical margin, fuscous brown; membrane hyaline with the veins pale brownish; antennæ, rostrum, body beneath, and legs pale cupreous; antennæ with the second joint longer than either third or fourth, which are subequal in length and a little darker in hue than first and second, fourth pale at base; pronotum with rather more than basal half thickly punctate, with an anterior broad smooth cicatrice not reaching the anterior margin ; scutellum punctate, the disk (so far as can be seen in typical specimen) less punctate; corium sparingly punctate, the scutellum longitudinally punctate.

Length $4 \frac{1}{2} \mathrm{~mm}$.
Hab. Bengal; Pusa (Lefroy).

## Abanus, gen. nov.

Head about as long as broad, angularly narrowed anteriorly, the central lobe prominent; ocelli near base and eyes; antennæ with the basal joint shorter than head but projecting beyond it, second joint a little longer than third, third and fourth subequal in length; rostrum reaching the intermediate coxæ, first joint very slightly passing base of head; pronotum clongate, about as long as broad at base, with a narrow anterior collar, the lateral margins nearly straight and moderately laminately reflexed, an obscure transverse impression a little behind middle; scutellum elongate, longer than broad; hemelytra long and narrow, membrane with the venation much as in Letheus; anterior femora moderately incrassate, finely spined beneath near apex; tibix spinuluse; tarsi with the basal joint as long or longer than the two remaining joints together.

To be placed near the genus Letheus.

## Abanus coloratus, sp. n.

Head, pronotum, and scutellum dull black; extreme lateral margins of pronotum more piceous than black ; apex of scutellum ochraceous; body beneath dull black; rostrum piceous brown, its basal joint and apex black; coxæ and legs more or less piceous brown; clavus pale piceous black, corium castancous, an inner line before clavus, lateral margin for about two-thirds its length, and a transverse fascia before apical area pale ochraceous, apical area black;
membrane piceous black and not quite reaching abdominal ap x ; antemme brownish ochraceous; structural characters as in generic diagnosis.

Length 9 mm .
Hab. Bengal ; Chapra (Mackenzie).

## Eremocoris nuini, sp. n.

Head, pronotum, and scutellum dull black; clavis and corium dull ochraceous, punctured and shaded with pieerous, the costal margin narrowly ochraccous, a rather distinct piceous spot near middle of costal area, and a similar, rather more obscure spot on disk near apex of clavus; membrane pale piceous, the posterior margin and reins greyish white, forming a looped linear spot near apical margin of corium ; borly beneath and femora black ; tibise, tarsi, and rostrum (excluding basal joint) brownish ochraceous; antenuc black, stout, first joint passing apex of head, about subequal in length to third joint, second joint considerably longer than either first or third, fourth joint mutilated in typical specimen; head very thickly punctate ; pronotum with the anterior lobe thickly fincly punctate, convex and longer than the posterior, which is flat and more coarsely punctate, the lateral margins sinuate at the transverse impression, anteriorly convexly rounded, the posterior angles a little thickened and slightly piceous brown; corium somewhat coarsely punctate, the pale narrow costal margin impunctate except at the region of the piceous central spot ; membrane scarcely passing the abdominal apex; rostrum reachiug or slightly passing the postcrior cosie.

Length 5 mm .
Hab. Kumaon; Naini Tal, 6400 ft .

## Manatanus, gen. nov.

Head about as long as broad, subacutely narrowed anteriorly, somerrhat longitudinally conically ridged above; antennæ with the first joint considerably extending beyond apex of head, second•joint a little longest, third and fourth almost subequal in length or third only slightly longer than fourth; rostrum almost reaching the posterior coxæ, first joint about reaching base of head; pronotum about as long as broad, transversely impressed a little behind middle, the lateral margins almost straight but roundly narrowed anteriorly, basal margin concare before scutellum; bemelytra scarcely extending beyond middle of abdomen, membrane
small; anterior femora incrassate and spined beneuth near apices; scutellum a little elevated.

In my enumeration of the Oriental Lygæidæ I place this genus near Lua, Dist.

## Manatanus montanus, sp. n.

Head, pronotum, and scutellum black; lateral margins of the anterior lobe of pronotum (broadened posteriorly) white; antennæ black; abdomen above and body beneath black; rostrum and legs ochraceous, basal joint of rostrum, anterior femora (excluding apices), more than apical halves of intermediate and posterior femora (excluding apices), and the tibiæ more or less black or piceous; clavus piceous brown, corium greyish white or pale stramineous, two elongate black spots before middle and the apex broadly black; membrane narrow, whitish, sometimes divided by black into two large whitish spots.

Var.-Posterior pronotal lobe more piceous brown than black ; first and second joints of antennæ piccous brown or ochraccous; intermediate and posterior femora and all the tibiæ ochraceous.

Length $4 \frac{1}{2} \mathrm{~mm}$.
Hab. Simla Hills; Mantiana (Ind. Mus. \& Coll. Dist.) ; Kumaon ; Naini Tal (Ind. Mus. \& Coll. Dist.).

This species was found under stones.

## Fam. Pyrrhocoridæ.

Abulfeda, gen. nov.
Head about as long as broad, anteriorly subangularly produced, the central lobe prominent; antenuæ robust, basal joint longest, almost as long as second and third joints together; pronotum gradually narrowed anteriorly, the lateral margins sinuate, transversely impressed before middle, anterior lobe raised and smooth, posterior lobe very coarsely punctate, transversely punctate before anterior margin, the anterior lateral margins ridged; scutellum triangular, smooth, almost obsoletely punctate; clavus and corium thickly strongly punctate; membrane not quite reaching abdominal apex; rostrum reaching the intermediate coxæ, basal joint about, or almost, reaching base of head ; anterior femora moderately thickened, shortly spined beneath.

This genus has the anterior area of pronotum completely circumscribed by continuous punctures and is allied to Euscopus.

Abulfeda punctatus, sp. n.
Head dull piceous black ; antenne piceous black, the base of the front joint pale stramincous; pronotum shining black, the lateral margins very narrowly and the posterior lateral angles more prominently ochraceous; scutellum piceous black, opaque; corium black, somewhat shining; membrane piceous black; body beneath dull, greyish black, opaque, the stigmata black; rostrum and legs testaccous brown; structural characters as in generic diagnosis.

Length 9 mm .
Hab. Ceylon; Peradeniya (Green).

## Euscopus albatus, sp. n.

Body and hemelytra piccous brown; membrane ochraccous brown; lateral margins of the pronotum and corium, and a short broad basal subcostal fascia to corium, ochraceous; an irregular transrerse fascia before apex of corium white with dark punctures; abdomen beneath more or less cretaceously tomentose, the stigmata black; legs brownish ochraceous, fourth joint piccous with the base pale stramineous, first joint almost as long as the second and third together, second and fourth subequal in length, each longer than third; head finely granulose and with a slight central longitudinal ridge; posterior pronotal lobe distinctly punctate, the lateral margins strongly sinuate, the transverse impression dividing the lobes profound, the anterior lobe a little raised and almost smooth; scutcllum and corium somewhat thickly punctate; rostrum almost reaching the posterior coxæ; anterior femora strongly spined beneath.

Length $8 \frac{1}{2} \mathrm{~mm}$.
Hab. Bombay (Dixon).

## Fam. Phymatidæ.

Glossopelta lineolata, sp. n.
Body above black; pronotum with the anterior lateral margins, a transwerse fascia (medially interrupted) between the humeral angles, the discal carination, and a small darkly punctate spot at base, ochraceous; scutellum with a central longitudinal line and some macular suffusions on the apical half ochraceous; connexirum, body beneath, legs, and rostrum pale ochraceous; head beneath black; antennæ brownish ochraceous, basal joint (excluding apex) and apex of apical joint black; membrane, as seeu on each side of
apical half of scutellum, violaceous; corium, as seen on each side of basal half of scutellum, black, posteriorly outwardly ochraceous; anteocular and postocular portions of head almost cqual in length, centrally longitudinally sulcately impressed behind eyes, apical joint of antemme about as long as the two preceding joints together ; pronotum coarsely punctate on the posterior half, two anteriorly curved carinations on disk, between which is a fine longitudinal sulcate impression, the lateral angles anteriorly very slightly directed forward, their apical margins a little concave; scutellum thickly finely punctate, coarsely punctate at base ; connexivum only visible at middle.

Length 10 mm .
Hab. Assam ; Khasi Hills (Lefroy). Burma (Coll. Dist.).

## Fam. Aradidæ.

## Mezira tenuicornis, sp. и.

Fuscous ; antemm, spinous antenniferous tubercles, posterior pronotal lobe and lateral margins of the anterior lobe, corium, connexivum, body beneath, and legs more fuscous brown; membrane greyish with dark veins, the lateral basal angles ochraceous; antennæ with the first, second, and fourth joints incrassate, third joint slender and much the longer ; head granulose, spines in front of eyes lons, acute, behind eyes tumid and distinctly laterally spined; pronotum granulose, the anterior asea sculptured, the anterior angles broadly, somewhat roundly, subangularly produced, the lateral margins sinuated before middle and roundly ampliated towards base ; scutellum granulose and subrugulose; corium granulose, the apical margins strongly sinuate, the lateral margins near base distinctly ampliated; membrane not quite reaching posterior margin of penultimate abdominal segment; abdomen above granulose; rostrum scarcely passing base of head.

Length 7-8 mm.
Hab. Simla Hills ; Mantiana, 8000 ft . (Annandale).
Near M. tenericornis, Bergr.
Under bark of fir (Annandale).

## Fam. Hebridæ.

## Hebrus bengalensis, sp. n.

Head black, with a greyish marginal line in front of eyes and a more or less ochraceous line at inner margins of eyes
finely pilose on basal area; pronotum dark castanenus, the anterior marginal area greyishly pilose, continued centrally towards middle by a wedge-shaped fascia; scutellum black; corium black, with short coarse pale hairs, a very prominent claval greyish fascia widening posteriorly and a curved more obscure greyish line before basal half of costal margin; membrane shining brownish, with a pale central subapical spot and a pale marginal line; body beneath black, legs pale ochraccous; antennæ dull ochraccous, with fine pale hairs, second joint shorter than first or third, fourth and fifth joints subequal in length; pronotum with the lateral margins strongly sinuate, the lateral angles prominent; scutellum with the apex angularly rounded, not incised.

Length 2 mm .
Hab. Lower Bengal (Coll. Dist.).

## Merragata pallescens, sp. n.

Head, pronotum, and scutellum pale cinnamon-brown ; corium ochraccous, the claval area milky white, base of costal margin narrowly black; membrane milly white, head beneath and sternum pale cimamou-brown; abdomen beneath piceous, legs and rostrum ochraceous; anteunie ochraceons, with fine hairs, third joint a little shorter than second, fourth piceous and about subequal in length to third; pronotum with the lateral margins strongly sinuate, the lateral angles broadly prominent, the basal margin moderately concave before scutellum; apex of scutellum broadly subtruncate, very slightly angulate on cach side, the disk transversely foveately depressed.

Length 2 mm .
Hab. East Bengal ; Rajshai (Annandale).
I have only seen a single specimen of this beautiful and distinctly marked species.

## Timasius, gen. nov.

Head moderately elongate, a little depressed anteriorly, with two central longitudinal ridges not reaching apex; eyes strongly granulate; antenniferous tubercles spinous externally ; antennæ five-jointed ; pronotum with the lateral margins strongly sinuate, the lateral angles broadly roundly prominent, transversely impressed before middle, and with two strong central longitudinal ridges; scutellum subtriangular, strongly, centrally, longitudinally ridged; corium and membrane subequal in length.

Allied to Hebrus, but differing in the more elongate body, the spinous antenniferous tubercles, and the centrally ridged head, pronotum, and scutellum.

## Timasius splendens, sp. n.

Head, pronotum, and scutellum black; pronotum with two central small spots of ochraceous hairs on anterior marginal area; corium bluish grey, with the margins, apical angle, a suboblong spot on disk, and the apex of clavus black; membrane dull blackish, with some greyish suffusions, the most prominent of which is a central subapical longitudinal line; body beneath black; legs ochraceous, the tibix and apices of femora and tarsi black ; antenns piccous or black, with short fine hairs, second joint slightly shorter than first, third and fourth subequal in length, each a little longer than fifth; pronotum sparingly coarsely punctate; scutellums finely granulose, the central ridge prominent ; other structural characters as in generic diagnosis.

Length 3 mm .
Hab. Ceylon; Peradeniya (Green).
"On rocks in mid-stream" (E. E. Green).

## Timasius atratus, sp. n.

Black ; legs pale ochraccous, posterior tibiæ pale piceons ; head opaque, with two central carinse terminating about oncthird before apex, antemiferous tubercles spinously proiduced, eyes strongly granulose; antenna ochraccous, pilose, first joint longer than seconf, a little shorter than third, fourth and fifth subequal in length, almost fused ; pronotum with its disk considerably mutilated in typieal specimen, but apparently bicarinate, the lateral margins strongly sinuate, the lateral angles roundly prominent; scutellum longitudinally carinate; pronotum, scutellum, and corium shining black; membrane piceous black, opaque; legs pilose.

Length $2 \frac{1}{2} \mathrm{~mm}$.
Hab. Ceylon; Madulsima (Bainbrigge-Fletcher).

## Fam. Hydrometridæ.

## Microvelia albomaculata, sp. n.

Dull piceous black with a greyish pubescence, which is more pronounced and forms a marginal fascia to head continued inside eyes to base and a submarginal fascia to pronotum; a reddish-ochraccous anterior narginal fascia
to pronotum, not reaching the anterior angles; hemelytia largely spotted with greyish white, of which a large spot occupies the greater part of clarus excluding apex, corium with two large basal marginal spots, three irregularly shaped spots in transverse series a little beyond middle, a large subapical membranal spot and a smaller subapical spot at inner margin; legs pale ochraccous ; antennæ fuscous, first joint very slightly longer than second or third joints, which are shortest and subequal in length, fourth longest, its apex distinctly acuminate; head subglobosely arched; lateral angles of the pronotum subangularly prominent; lateral margins of the hemelytra concarely sinuate and finely shortly hirsute; apices of tibise and tarsi more or less obscurely fuscous.

Length 2 mm .
Hab. E. Bengal ; Rajshai (Amandale).

## Microvelia kumaonensis, sp. n.

IIead, pronotum, and body beneath dull black; apex of head, anterior margin of pronotum (centrally interrupted and not reaching anterior angles), margin of lateral pronotal angles, legs, and rostrum pale ochraceous; lateral margins of head, continued inside eyes to base, greyishly fasciately pubescent; hemelytra pale piceous brown, with prominent grevish-white spots, an elongate spot in clarus, a large subbasal spot to corium, more obscure spots on apical half of corium, and a prominent subapical spot ; antenne brownish ochraceous, second joint slightly shorter than first and distinctly shorter than third, fourth longest; head subglobosely arched ; pronotum with the lateral angles broadly subacutely prominent; apices of tibix and tarsi more or less pale piceous.

Length 2 mm .
Hab. Kumaon; Bhim Tai.

## Microvelia diluta, sp. n.

Head and pronotum dull black ; anterior margin of pronotum reddish ochraceous; hemelytra dull greyish white, the reins piceous, the apical area darker and thus exhibiting a large pale apical spot; body beneath and legs dull pale ochraceous ; rostrum, disk of sternum, apices of femora, tibiæ (more or less), and the tarsi piceous; antenur with the first, second, and third joints ochraceous, their apices and the whole of the fourth joint picenus, second joint
slightly shorter than first, more distinctly shorter than third ; head globosely arched; pronotum with the lateral margins sinuate, the lateral angles subangularly prominent; hemelytra scarcely reaching the abdominal apex; connexirum granulose and pilose.

Length $2 \frac{1}{2} \mathrm{~mm}$.
Hab. Bengal ; Calcutta, Rajshai (Annandale).
"Stridulates when irritated, producing a shrill scrapiug sound which is perceptible for some yards. Feeds on dead insects. Winged and apterous indiriduals occurring together." (Nelson Annandale, in litt.)

Allied to $M$. repentina, Dist., but colour of antennæ and body beneath different. In some specimens the lateral margins of the abdomen beneath are piceous.

## Microvelia annandalei, sp. n.

Head and pronotum dull black; pronotum with a transverse dull ochraceous subanterior fascia not reaching the lateral margins (this fascia is frequently discoloured and difficult to recognize); hemelytra piceous, a basal claval streak, and three spots on apical area (the apical spot linear) dull greyish with a greenish tint; body beneath black; head beneath, margins of prosternum, lateral margins of abdomen, and the legs, ochraceous; antennæ with the first, second, and third joints ochraceous, apices of first and second and the whole of the fourth joint piceous, second joint distinctly shorter than either first or third, third and fourth subequal in length; head with the apex ochraceous and a pale lougitudinal line at inner margins of eyes; extreme apices of the femora and sometimes the intermediate and posterior tibiæ more or less infuscate; lateral angles of the pronotum broadly subprominent.

Length 2 mm .
Hab. Lower Bengal ; Port Canning (in brackish pools).

## Fam. Reduviidæ.

## Eyestife.

Ploiariola mixta, sp. n.
Head cinnamomeous, clothed with a greyish pubescence, eyes black; antennre pale stramineous; pronotum cinnamomeous, the anterior area and lateral margins speckled with greyish; body beneath and rostrum piceous, the apical joint of the latter pale stramincous; anterior legs pale
cinnamon-brown, the femora and tibire annulated with pale greyish; intermediate and posterior legs pale stramineous; hemelytra greyish, thickly speckled and spotted with pale brownish, three prominent dark spots on costal margin, the first at about one-third from base, the sccond near middle, the third before apex; claval area thickly spotted; scutellum spined at base and apex.

Length 7 mm .
Hab. Ceylon; Peradeniya (Green).
Allied to $P$. oculata, Reut., but with the pronotum narrower and more elongate; intermediate and posterior legs unspotted; hemelytra much darker and altogether differently spotted and marked.

## Ploiariola polita, sp. n.

Head greyishly pubescent, finely spotted with black; antennæ mutilated in typical specimen; pronotum with the anterior area greyish white spotted with black, the posterior area yellowish grey, with a central line, the lateral margins (narrowly), and the basal margin (broadly and sinuately) ochraceous ; rostrum pale stramineous spotted with brown; prosternum chocolate-brown, the margins ochraceous; mesoand metasterna black, greyishly tomentose ; abdomen mutilated in typical specimen; anterior legs grevish, coxæ, femora, and tibiæ spotted with brownish, intermediate and posterior legs thickly spotted with brownish; hemelytra pale greyish white, claval and basal areas, the basal divisional membranal reins, and the apical and inner margins spotted with brownish, the pale areas indistinctly and subobsoletely spotted; scutellum spined at base and apex.

Length 7 mm .
Hab. Ceylon; Hakgala (Green).
This is to be differentiated from the previous species and those enumerated and described in the Faun. Brit. Ind. by the more subquadrate pronotum, the thickly spotted intermediate and posterior legs, and the very distinct pattern and markings of the hemelytra.

## Calphurnia, gen. nov.

Head with the postocular area considerably longer than the anteocular area, rounded, convexly narrowed at base, transversely constricted between the eyes, and with a more or less distinct basal collar; antennæ with the first joint as long or longer than the head, pronotum, and scutellum together, second joint a little shorter than third ; rostrum
passing base of head, basal joint reaching but not passing eyes; pronotum elongate, narrowed auteriorly, with a prominent anterior lobe distinctly diviled above and bencath; scutellum not spined; hemelytra with the corium distinctly transversely veined, the central membranal veins posteriorly and lobately united, membrane slightly passing the abdominal apex; anterior coxx shorter than the femora, which are again longer than the tibiæ; intermediate and posterior legs long and slender ; anterior tarsi three-jointed ; legs in typical form somewhat longly spinulose, but this does not appear to be a constant character.

This genus has a superficial resemblance to Ploiariola, from which it differs by the different shape of the head, the distinct anterior lobe of the pronotum, the non-spinous scutellum, the transversely veined corium, and the distinctly veined membrane, \&c.

## Calphurnia reticulata, sp. n .

Body and legs pale ochraceous; hemelytra greyish white, the venation fuscous; membrane with the basal area speciled with plumbeous and its apical and inner area spotted with the same colour ; antennæ a little darker and more brownish in hue, first joint subequal in length to that of the head, pronotum, and scutellum together, second joint a little shorter than third; head distinctiy transversely impressed between eyes and slightly pedunculate at base ; pronotum with the anterior lobe about half the length of posterior lobe, which is moderately widened towards base ; anterior coxæ faintly and anterior femora distinctly annulated with brownish near apex, intermediate and posterior legs distinctly finely spinulose; hemelytra scarcely passing the abdominal apex; other structural characters as in generic diagnosis.

Length 5 mm .
Hab. Calcutta. Ceylon ; Peradeniya (Green).

## Calphurnia ? aberrans, sp. n.

Body and legs pale greyish brown; hemelytra greyish white, somewhat thickly spotted and speckled with plumbeous, the venation fuscous; antennæ with the first joint about as long as the intermediate femora, second joint shorter than first, but much longer than third; head narrowed at base, but not distinctly pedunculate, transversely compressed between the eyes; pronotum with the anterior lobe more than half the lengtl of the posterior lobe, which is a little
widened towards base ; apex of anterior coxæ and annulatious to anterior femora and tibiæ brownish, posterior femora with two blackish annulations-one before, the other near middle; legs not spinulose ; hemelytra slightly passing the abdominal apex; sternum and head beneath more or less piceous.

Length $6 \frac{1}{2} \mathrm{~mm}$.
Hab. Ceylon; Peradeniya (Green).
This species, by the longer anteune and different proportional length of joints, the longer anterior pronotal lobe, and the non-spinulose legs, differs from the typical form of the genus as represented by C: reticulata. The distinct renation of the hemelytra is, however, maintained, and I have provisionally included it in Calphurnia.

## Elymas, gen. nov.

Head strongly narrowed at base, transversely impressed between eyes, anteocular a little shorter than postocular area; rostrum reaching the anterior coax, first joint short, not reaching eyes, second longest ; antennæ long, slender, first joint longest, about as long as from apex of mesonotum to apex of abdomen, second joint shorter than first and about as long as abdomen; pronotum elongate, a little widened at apex and a little shorter than anterior coxæ ; mesonotum laterally sinuate, moderately widened posteriorly; apterous; abdomen above with the lateral margins recurved and ridged, almost mecting on apical area, the apical appendage globosely elongate and apically concavely excavate; anterior femora about one-third longer than the anterior coxæ, slightly attenuated at junction with trochanters, moderately sinuate on basal half, finely spinulose beneath for nearly their entire length; anterior tibiæ about half the length of the femora; anterior tarsi single-jointed, about onefourth shorter than the tibiæ; intermediate and posterior legs long, slender, posterior femora slightly curved and nearly as long as the whole body, the tibire considerably longer than the femora, the posterior legs longer than the intermediate legs.

## Elymas presentans, sp.n.

Body above brownish ochraceous; lateral margins of head behind eyes, lateral margins of thorax abore, lateral margins of abdomen above, and the anal appendage black; body beneath black; rostrum brownish ochraceous with black
annulations; anterior corx and legs piceous, a subapical annulation to femora and the base of the tarsi ochraceous; intermediate and posterior legs brownish ochraceous, becoming piceous towards apices, apices of femora and bases of posterior tibire, and a subapical annulation to intermediate tibir, pale greyish; antennæ piceous; structural characters as in generic diagnosis.

Length 12 mm .
Hab. Ceylon; Kandy (Green).

## Plæaria anak, sp.n.

More or less pale ochraceous; vertex with a transwerse fascia in front of eyes counceted with tiro central lines extending to base, brownish ochraceous; a lateral longitudinal fascia on each side of pronotum and two short central lines to both meso- and metanota bromnish ochraccous; abdomen above with more or less distinct central longitudinal segmental lines, on each side of which are small dats and spots to connexivum, fuscous; a spot near apex of anterior cocæ, two large lateral spots on each side of auterior femora, a spot on each side of base of rostrum, and an annulation to basal joint of same fuscous brown, apical joints of rostrum pale brownish; abdomen beneath with the lateral margius irregularly pale brownish; antennæ a little darker in hue, first and second joints subequal in length and each about as long as abdomen; rostrum with the basal joint passing eyes ; pronotum elongate, about as long as meso- and metanota together, anteriorly roundly dilated, the anterior margin truncate; abdomen strongly attenuated at base, beyond basal segment gradually ovately widened and again narrowed towards apex ; intermediate and posterior femora a little darker in hue with their apices pale ochraceous; anterior trochanters with a single strong prominent spine.

Length 11 mm .
Hab. Lucknow (Aitken).

## Gardena fasciatr, sp. n.

Head, pronotum, and mesonotum chocolate-brown, pronotum with a broad sublateral greyish fascia on each side, mesonotum with three central greyish fasciæ, the central fascia broadest, the lateral fasciæ narrower; hemelytra greyish brown; head beneath and sternum black, the latter grevishly tomentose ; legs greyish brown, coxæ (excluding apices) and trochanters shining black; abdomen above and beneath greyish piceous; antennæ mutilated in typical Ann. \& Mag. N. Hist. Ser. 8. Vol. iii.
specimen; head about as long as mesonotum, shorter than pronotum; hemelytra extending to the base of the penultimate abdominal segment ; anterior femora palely amulate near apex, finely spinose bencath from about one-third from base, anterior tarsi three-jointed; rostrum reaching the base of the anterior coxx, basal joint incrassate, darker than the remaining joints ; intermediate tibiæ apically palely anuulate, intermediate and posterior tarsi mutilated in typical specimen.

Length 15 mm .
Hab. Ceylon ; Paradeniya (Green).
I have only seen an incomplete specimen of this wellmarked species.

## Tribeloceptalinta.

## Opisthoplatys cornutus, sp. n.

Head, antennæ, pronotum, connexirum, body beneath, rostrum, and legs ochraceous; scutellum and corium fuscous brown, basal and apical angles of the latter ochraceons; membrane piceous black; eyes black; antennæ longly pilose, first joint about as long as anterior femora, second joint slightly longer than first, the antenniferous tubercles above produced in short, prominent, slightly forwardly curved tuberculous spines; rostrum with the basal joint reaching but not passing eyes; pronotum with the anterior lobe ouly a little more than half the length of posterior lobe; scutellum granulose ; corium distinctly longitudinally broadly ridged, the costal ridge more prominent and not quite reaching apical angle, a second prominent discal ridge, and a subclaval less prominent ridge, between the ridges the colour is brownish ochraceous; membranal veins a little ochraceous at base.

Length 8 mm .
Hab. Travancore; W. Ghats, Tenmalai.

## A pocaucus, gen. nov.

Head with the anterior lobe moderately porrect and a little produced in front of eyes, but clothed with long curled hairs, somewhat flattened on disk but longly produced and apically curled downward at their apices on lateral and anterior margins ; antennæ pilose, first joint about as long as head, second shorter than first, remaining joints very slender; rostrum reaching the anterior coxæ, first joint reaching eyes, but not extending behind them: pronotum
narrowed anteriorly, the basal area centrally sulcately impressed, on each side of which are two callosities making a transverse series of four in all, the central ones largest; scutellum callous at base; elytra longly passing the abdominal apex; legs slender, pilose, intermediate and posterior tibix almost equally wide apart.

This very peculiar genus is to be readily separated from Tribelocephala and Opisthoplatys by the long fleecy clothing to the head.

## Apocaucus laneus.

Head and pronotum castaneous brown, the long fleecy clothing to the former pale brownish; scutellum and elytra fuscous brown, the latter with the marginal areas paler ; body beneath and legs pale castaneous brown, the femora paler and more brownish ochraceous; abdomen beneath smooth and slining ; legs and antenne finely pilose.

Length $5 \frac{1}{2} \mathrm{~mm}$.
Hab. E. Himalayas ; Kurseong.
Closely resembles a Monophlebus on the wing ( $N$. Annandale).

Postscript.-The title of this paper, "Oriental Khynchota," signifies Rhynchota from the Oricutal Region as generally understood in zoo-geography. The term, however, appears to be sometimes used inexactly, as quite recently (Ann. Soc. Ent. Belg. 1909, p. 184), under the heading "Hemiptera nova orientalia," Bergroth describes species from Australia, Tasmania, and New Caledonia.
LXVI.-New Land, Freshwater, and Mreine Shells from South America. By H. B. Preston, F.Z.S.
[Plate X.]
Glandina chanchamayoensis, sp. n. (Fig. 7.)
Shell fusiform, pale flesh-colour ; whorls $6 \frac{1}{2}$, somewhat flattened, regularly increasing in size, coarsely, transversely striate, with lines of growth and sculptured with fine, spiral striæ, presenting a decussate appearance ; sutures impressed, narrowly margined, crenulate; columella curved, rather abruptly truncate; peristome simple, whitish; aperture elongately, inversely auriform.

Alt. 68.25, diam. maj. 27 mm .
A perture: alt. $35 \cdot 5$, diam. $12 \cdot 5$.
Hab. Chanchamayo, Peru.
I am unable to find that any species at all approaching this in size and sculpture has yet been recorded from Peru.

## Glandina venezuelensis, sp. n. (Fig. 10.)

Shell somewhat acuminately fusiform, light reddish brown ; whorls 7, the first four smooth, polished, the remainder marked with coarse, closely set, irregular, transverse riblets crossed by fine, wavy, spiral strixe; sutures impressed, crenulate; columella elongate, descending in an oblique curve; peristome thin; aperture elongately, inversely auriform.

Alt. 54, diam. maj. 21 mm .
Aperture: alt. 28 , diam. 10 mm .
Hab. Merida, Venezuela.
Allied to G.decussata, Desh., from Mexico and Texas; the spiral sculpture in the present species is, however, finer, and the transverse riblets are coarser, it is also of a larger size, the aperture is broader and the columella is less twisted above and is longer and straighter than is the case with G. decussata.

## Solaropsis venezuelensis, sp. n. (Fig. 12.)

Shell depressed, thin, reddish hom-colour, painted with three narrow, interrupted, spiral bands and numerous transverse flame-markings of reddish purple; whorls $4 \frac{1}{2}$, closely hispid; sutures deeply impressed; umbilicus narrow and deep ; aperture rather obliquely lunate; peristome reflexed, yellowish white, margins somewhat distant; columella descending obliquely and reflexed, thus partly concealing the umbilicus.

Alt. $7 \cdot 25$, diam. maj. $18 \cdot 5$, diam. min. 12 mm .
Aperture : alt. 7 , diam. 6.5 mm .
Hab. Merida, Venezuela.
Epiphragmophora anceyana, sp. n. (Figs. 14 A, 14 B.)
Shell moderately solid, discoidal, depressed, white, bearing traces of having been encircled by three narrow chestnut bands ; whorls $4 \frac{1}{2}$, striate, with fine lines of growth, the last whorl descending somewhat abruptly; sutures impressed, chalky white; umbilicus wide, open, deep; aperture subcircular ; peristome thickened, dilated, slightly reflexed, the margins joined by a thick parietal callus.

Alt. 12, diam. maj. 25, diam. min. 20.5 mm .

Aperture : alt. 13 , diam. 14 mm .
Hab. Argentina.
The only species which in general outline approaches the present form is E. macasi, Higg., from Ecuador ; this, however, is easily distinguished by its mach larger size from that now described.

Bulimus (Eurytus) dissimulans, sp. n. (Fig. 5.)
Shell imperforate, ovate, thin, brown, painted with very closely set, greyish-yellow, wavy, transverse lines, and indistinct, brownish, spiral bands ; whorls $3 \frac{1}{2}$, rapidly increasing in size, rather flat, smooth; sutures impressed; columella arched ; peristome slightly thickened, rose-coloured; aperture ovate, somewhat laterally contracted.

Alt. 30 , diam. maj. 15 mm .
Aperture: alt. 18, diam. 11 mm .
Hab. Merida, Venezuela.
The extraordinary painting of this species at first gives the impression that the shell is closely, vertically, striate; this, however, is not the case, the appearance being caused by the closely set, greyish-yellow, transverse colour-lines.

## Bulimus (Thaumastus) insolitus, sp. n. (Fig. 9.)

Shell imperforate, obtusely fusiform, solid, ground-colour dark blackish brown ; extreme apex sunken; whorls $5 \frac{1}{2}$, flattened, the earlier whorls sculptured with very fine, wavy, transverse striæ, presenting an almost finely granular appearance, the later whorls very coarsely sculptured with transverse ridges crossed by fine, spiral grooves, giving to this portion of the shell a finely beaded appearance, the rows of beaded tubercles being of a yellowish-brown colour, last whorl descending rather rapidly, from the point where the last whorl begins to descend there occurs a supersutural band about three millimetres broad, continued as a peripheral band, and increasing to six millimetres in breadth on the last whorl, on this band the beaded sculpture is less marked and the surface of the shell is of a correspondingly more uniform blackish-brown colour ; sutures impressed, crenulate, whitish, especially towards the latter half of the last whorl ; columella thick, slightly excavated; peristome lightly, varicosely thickened, brownish yellow, somewhat reflexed below; the margins joined by a thick, polished, brown callus; aperture ovate.

Alt. 70, diam. maj. 29.5 mm .

Aperture: alt. 33, diam. 16 mm .
Hab. Chanchamayo, Peru.
An extrandinary shell which it is not possible to compare profitably with any species at present known; the sculpture is of the type of that of Thaumastus melanochila, Nyst, which also occurred with it, but is much coarser ; the much blunter form, sunken apex, and total absence of any trace of perforation are also among the characters which readily separate it from that or any other known species.

Among the shells received from Chanchamayo, Peru, is a good specimen of what is undoubtedly Bulimus lulcherrimus, II. Ad.: the only specimen of this fine species hitherto seen is, I believe, the type specimen in the British Museum consisting of the last two and a half whorls of the shell, which are figured in the Proc. Zoul. Soc. 1566, p. 442, pl. xxxviii. fig. 3 ; as this figure is naturally somewhat inaderinate I take this opportunity of figming the specimen (Pl. X. fig. 6) which has recently come to hand.

## Bulimulus latecolumellaris, sp. n. (Fig. 11.)

Shell cylindrically fusiform, perforate, moderately thin, whitish, indistinctly bauded and transversely tessellated with pale reddish brown; whorls 8, slightly convex, embryonic whorls smooth, later whorls lightly marked with lines of growth and very faintly decussate; sutures deeply impressed, slightly crenulate; umbilicus obliquely lunate, very narrow, deep, the whole umbilical region pure white ; columella white, outwardly expanded, extended into a very bread twisted plait above, much excavated below; peristome white, expanded, scarcely reflexed, a light callus joining the margins; aperture obliquely inversely auriform.

Alt. 54, diam. maj. 24 mm .
Aperture : alt. 22.5 , diam. 15 mm .
Hab. Peru.
Allied to B. tupaci, d'Orbigny, from Bolivia, but much smoother in general appearance, the umbilical region is quite without colour, and the embryonic whorls are not punctate as is the case in that species, moreover the extraordinary broadly plaited columella easily separates it from $B$. tupaci.

## Bulimulus (Drymeeus) expatriatus, sp. n. (Fig. 4.)

Shell fusiform, acuminate, narrowly perforate, somewhat thin, pale yellow; whorls $6 \frac{1}{2}$, finely spirally striate, and marked transversely with lines of growth; sutures impressed,

Whitish; peristome thin, slightly reflexed; columella desconding obliquely over the narrow umbilicus and suffused into a very thin callus, which joins the lip above; aperture inversely auriform.

Alt. 28, diam. maj. 11.5 mm .
Aperture: alt. 12, diam. 5.5 mm .
Mab. E. Bolivia.
'i'he above species recalls in many ways Bulimulus liliucens, Fér., from Porto Rico; among the shells received from Bolivia at the same time there are a number of specimens which would appear to be the young of the present species; some of these are stained with bright pink about the umbilical region, a character which is totally lacking in the adult shell.

## Bulimulus (Drymeres) interruptus, sp. n. (Fig. 1.)

Shell fusiform, thin, semitransparent, yellowish white, painted with five reddish-purple bands, the first four of which are broken up so as to appear as rows of squarish blotches, the fifth uninterrupted; whorls $5 \frac{1}{2}$, rather Hat, transversely sculptured with lines of growth; sutures impressed ; columella somewhat arched and reflexed over the very narrow perforation; peristome acute, slightly reflexed, especially towards the base; aperture oval.

Alt. $25^{\circ} 5$, diam. maj. $10^{\circ} 5 \mathrm{~mm}$.
Aperture: alt. 11, diam. 6.5 mm .
Hab. Merida, Venezuela.
The shell appears to be greatly variable; its principal forms are mentioned below.

Form " $\alpha$."-Painted with transverse bands of reddish purple, interrupted for a space of about $1 \frac{1}{2} \mathrm{~mm}$. at the periphery; the last band, which is uninterrupted in the type, is absent in this form.

Form " $\beta$."-Transverse bands more closely set and uninterrupted ; ground-colour of shell flesh-colour.

Var. pallidus, nov. (Fig. 2.) -Shell of a uniform yellowishwhite colour, smoother than the type, the growth-lines being not nearly so noticeable.

Var. pallidus, form " $\gamma$."-Flesh-coloured throughout.
Var. pallidus, form" $\delta$."-Pale yellow throughout.
Bulimulus (Drymceus) selli, sp.n. (Fig. 3.)
Shell fusiform, narrowly perforate, very thin, vitreous,
painted with interrupted bands and transverse zigzag flamemarkings of rich chocolate; whorls 5 ${ }_{2}^{2}$, sculptured with fine regular spiral striæ and marked with ${ }^{\text {- fine }}$ indistinct lines of growth; sutures well impressed; columella arched, reflexed over the narrow umbilicus; peristome acute, somewhat broadly reflexed; aperture oval.

Alt. 24, diam. maj. 13 mm .
Aperture : alt. 11, diam. 6 mm .
Hab. British Guiana.

## Orthalicus powissianus, Petit, var. niveus, nov.

Shell pure white, bearing only a very faint trace of the infra-peripheral band; lower portion of the columellar callus slightly stained with very pale brown ; outer lip and interior of shell pure white.
'laken with the animal alive by Mr. Mervyn G. Palmer at Jimenez, Rio Dagua, West Culombia.

## Planorbis pucaraensis, sp. n. (Fig. 15.)

Shell suborbicular, very depressed above, basally somewhat convex, blackish brown; spire slightly concave; whorls 3, rapidly increasing in size, sculptured with strong, transverse, arcuate lines of growth; sutures impressed ; umbilicus moderately wide above, narrow and deep below; columella oblique, extending into a thin callus above; peristome simple, acute; aperture broadly sublunate.

Alt. 25 , diam. maj. 6.75 , diam. min. 5.5 mm .
Aperture: alt. 2, diam. 2 mm .
Hab. Pucara, Peru, at an altitude of 12,500 feet.

## Nassa flammulata, sp. n. (Fig. 13.)

Shell fusiform, moderately solid, pale yellowish painted with transverse streaks of reddish brown, which appear as flame-markings on the upper whorls; whorls 6 , the first five spirally grooved, the grooves being more noticeable above; the last whorl transversely ribbed, the ribs being formed into rows of tubercles by the spiral grooving, which is more uniform on this whorl; sutures well impressed; columella slightly excarated and extending into a callus, which joins the lip above; peristome simple, but not acute; canal short and wide ; aperture inversely auriform.

Alt. $13 \cdot 25$, diam. maj. 7 mm .
Aperture : alt. 5, diam. 2.5 mm .
Hab. S. Peru.

There is a fine series of this species in the British Mruseum, received in 1854 under the name of "Buccinum bolivianum," and labelled as coming from Cobija, which place is now well within Chilian territory, though formerly belonging to the Republic of Bolivia; as I am unable to trace the name "bolivianum" in any work, I have thought it well to describe and figure the species as above.

## Paludestrina valencice, sp. n. (Fig. 16.)

Shell small, perforate, fusiform, smooth; whorls 5, very convex; sutures deeply impressed; umbilicus narrow; peristome simple; aperture roundly ovate.

Alt. $2 \cdot 5$, diam. maj. 1.25 mm .
Aperture : alt. 25 mm .
Hab. Lake Valencia, N. Venezuela.

## Mycetopus punctatus, sp. n. (Fig. 8.)

Shell elongate, thin, covered with a pale olive periostracum, and exteriorly sculptured with faint strie radiating from the umboes; umboes inconspicuons; anterior end rounded, gaping; posterior end produced, acuminate below; dorsal margin straight; ventral margin slightly convex; interior of shell nacreous, marked throughout with very fine radiating punctate striæ.

Long. 21.5 , lat. 72 mm .
Hah. Rio Chenchi, U.S. Colombia.

## LXVII.-Four new African Mammals. By R. C!. Wroughton.

In my note on the forms of the small African mon ooose with a dark-tipped tail (Ann. \& Mag. Nat. Hist. 1907, xx. p. 110) I arranged those of North-east Africa as subspecies of Mungos sanguineus, Rüpp. Recently Mr. L. DI. Seth-Smith has presented to the National Cullection two specimens from Uganda, which, while differing inter se, agree in having unicoloured feet, a character which distinguishes them from all the four forms enumerated by me. In my key therefore all the forms dealt with may be included in a subsection characterized by having grizzled feet, while the two new races, to be now described, constitute a second subsection, as follows :-

Hands and feet unicoloured ochraceous.
Size smaller: hind foot 58 mm . Colour darker (raw umber). (Entebbe.)...... M. s. uganda, subsp. n.
Size larger: hind foot 64 mm . Colour paler (tawny ochraceous). (Mubende.) .... M. s. galbus, subsp. n.

Mungos sanyuineus uganda, subsp. n.
Alont the size of If. s. iberr. Fur medium ( 15 mm . long on lack). Colour above "clay-colour," variegated with black, giving a general effect near raw umber, below " claycolour." Individual hairs of the back basally drab for $\frac{1}{3}$ their length, distally " clay-colour," with a sulterminal black ring ( $2-3 \mathrm{~mm}$. wide), darkening again towards extreme tip. Crown, face, and cheeks fincly grizzled buff and black. Hands and feet "tawny ochraceous." Tail coloured like back, with a black tip $60-70 \mathrm{~mm}$. long.

Skull as in ibece.
Dimensions of type (measured on the skin) :-
Head and body 330 mm . ; tail 290 ; hind foot 58.
Skull: condylo-basal length 66 ; basilar length 60 ; zygomatic breadth 33 ; brain-case breadth 27 ; palate, breadth across $p^{4} 22$, length $c-m^{1} 21 \cdot 5$.

Hab. Entebbe, Uganda.
Type. Adult male. B.M. no. 9.5.12.1. Collected 18th July, 1908.

Mungos sanguineus galbus, subsp. n.
Size larger than any other known form of sanguineus. Ground-colour bright ochraceous, variegated on the back with
black, which becomes obsolescent on the flanks and is entirely absent on the throat, chest, and belly. Individual hairs bright ochraceous buff, with a short greyish-white base, and those of the back with a subterminal black ring. Crown and face finely grizzled ochraceous and black, the black obsolescent on the cheek, entirely absent on the upper lip. Entire fore legs and hind feet ochraceous like the belly. Tail coloured like back, with a black tip (apparently mutilated in the type specimen).

Skull unfortunately missing.
Dimensions of the type (measured in the flesh) :-
Head and boty 345 mm .; tail 270 ; hind foot 64 ; ear 28.
$H a b$. Mubende, Uganda.
Type. Adult male. B.11. no. 9. 5. 12.2. Original number 45. Collected 7th April, 1908.
'This animal curiously resembles M. auratus, from Tette, in colouring, except that the tawny suffusion on head and face, so characteristic of all the forms of this group found south of the Zambesi, is entirely absent. Its size and colouring distinguish it at once from any other subspecies of sanguineus.

When working out the Rull Collection in conjunction with Mr. Thomas, we were able to distinguish two wellmarked local 1aces of Paraxerus cepapi (P. Z. S. 1908, p. 543), a southem and a northern. An examination of the material in the Natural History Museum ('ollection shows that there are at least two other races north of the Zambesi which merit description. 'They are:-

## Paraxerus cepapi soccatus, subsp. n.

A local form about the same size as typical cepapi, less brightly coloured, and with somewhat stouter teeth and a shorter broader skull.

Colour-pattern as in true cepapi, but the yellow suffusion, especially on the limbs and flanks, so characteristic of cepopi entirely absent. Hands and feet greyish white.

Skull short and broad ; nasals short ; teeth stout.
Dimensions of the type (measured on the skin) :-
Head and body 190 mm. ; tail 160 ; hind foot 41 ; ear 20 .
Skull: greatest length 42 ; basilar length 32 ; zygomatic breadth 26.5 ; brain-case breadth 21 ; nasal. 11.5 ; palatilar length 17; diastema 9 ; upper molar series (exclusive of $\left.p^{3}\right) 7 \cdot 8$.

Hab. N. Angoniland (type from Vwaza, IIcwe R.).

Type. Adult male. B.M. no.7.2.4.6. Original number S63. Collected by Mr. C. B. C. Storey on the 11th Septeniber, 1906.

Four specimens, three males and one female (including the type), taken together on the same day, are very like one another in all essential features, one only amongst them showing a rusty suffusion all over the body due to bleaching. The constant absence of buffy colonring on the hands and feet is very noticeable. The disproportionate breadth of the skull is equally present in all four specimens.

Some specimens from the adjoining Nyasa-Tanganyita Plateau appear to belong to this race.

## Paraxerus cepapi quotus, subsp.n.

About the size of typical cepapi. Colouring much darker and suffusion of colour on flanks and thighs wanting.

Culour-pattern as in true cepapi, but the marked suffusion of buffy on the flanks and thighs entirely alsent, that on fore limbs darker. Hands and feet suffused with buffy, but to a less extent than in cepapi.

Skull broad for its length, but not so markedly so as in the Angoni form ; nasals longer and narrowed anteriorly; teeth as in the Transvaal form.

Dimensions of the type:-
Head and body 190 mm.; tail 178 ; hind foot 42 ; ear 21.
skull: greatest length 44; basilar length 35 ; zygomatic hreadth 26 ; brain-case breadth 20 ; nasals 13 ; palatilar length 1855 ; diastema 10 ; upper molar series (exclusive of $\left.p^{3}\right) 7 \cdot 8$.

Hab. Katanga Dist., Congo State.
Type. Adult male. B.M. no. 7. 12. 13.16. Original number 23. Collected by Mr. S. A. Neave on the 1 th March, 1907.

T'wo specimens, both of which show the markedly dark colouring which makes them distinguishable at sight from any other form.

The forms of $P$. cepapi may be arranged in a bey as follows:-
A. Size larger: hind foot 42 mm .
a. Hands and feet suffiused with buffy.
$a^{2}$. Shoulders, flanks, and thighs suffused
with orange-buff. (Limpopo Basin.) . $\quad$. cepapi, A. Sm.
$b^{1}$. Buffy suffusion on flanks and thighs absent, that on shoulders reddish brown. (Katanga Dist., Congo State.) P. c. quotus, subsp. n.
b. Hands and feet greyish white $\ldots . . . .$. . P. c. soccatus, subsp. n.
B. Size smaller : hind foot 39 mm . (Zambesi

Basin.)
P. c. sindi, T. \& W.
LXVIII.-On some new Species of Coleoptera from Rhonesi: and adjacent Territories. By Gilbert J. Arrow.
(Published with the permission of the Trustees of the British Museum.) The following notes and descriptions are incidental to the systematic study of two important collections recently added to the British Museum, that of Mr. S. A. Neave from NorthEast Rhodesia and the Katanga District of the Congo Free Slate, and another presented by Mr. Guy A. K. Marshall and made by him or on his behalf in Mashonaland and the part of Portuguese East Africa immediately alijoining.

## Copridæ.

## Sisyphus callosipes, sp. n.

Niger, opacus, undique minute sat dense griseo-setosus; capite grosse punctato, clypei margine antico profunde semicirculariter exciso, dentibus 2 internis prominentibus, externis subobsoletis; prothorace leviter varioloso-rugoso, postice medio lineato-sulcatulo, lateribus ante medium fortiter convergentibus, angulis anticis acutis, deinde paulo sinuatis, dorso convexo; elytris sat -egulariter striatis, ad apices valde attenuatis ; pedibus gracilibus, haud spinosis, trochanteribus haud productis; metasterno nitido, profunde impresso:
$\delta$, tibiis anticis sat robustis, subtus haud dentatis, pedibus intermediis simplicibus, pedum posticorum femoribus clavatis, postice medio callo lato, nitido, instructis, tibiis longis, curvatis, intus serratis, extremitate intus abrupte dilatato.
Long. 10-11 mm. ; lat. max. $6-7 \mathrm{~mm}$.
Hab. German East Africa: Massailand; British Central Africa: Nyasaland; Katanga, 150-200 miles west of Kambove; Mashonaland: Chirinda.

The female of this is like the common Sisyphus crispatus, Gory, but it is a larger species, the upper surface is less rugose and clothed with a finer and closer pubescence. In the male the hind trochanters are not produced and the front
tibia is not furnished with teeth beneath; the hind femur is flattened, broad in the middle and bars a broad shining laminar appendix at its lower edge ; the hind tibia is strongly curved, serrate within and has also a small laminar immer appendix at its extremity.

## Sisyphus gazanus, sp. n.

Niger, opacus, supra ferrugineo-indutus, setis erectis ferrugineis undique tectus; clypeo antice dentibus 2 acutissimis internis armato, externis subobsoletis; prothorace sat longo, lateribus fere parallelis, paulo ante angulos anticos dentatis et deinde convergentibus, angulis anticis acntis, dorso parum convexo; elytris sat regulariter costatis, pone humeros latis, lateribus deinde leviter arcuatim contractis; pedibus gracilibus, haud spinosis, trochanteribus haud productis :
$\delta$, tibiis posticis curratis, intus serratis ; clypei dentibus 2 internis remotis, intervallo haud angulato:
of clypei dentibus 2 internis haud remotis, intervallo angulato.
Long. 5-6 mm. ; lat. max. 3-4 mm.
IIab. Gazaland: Chirinda, Chibababa (Oct., Nov., Dec., 1901-1906).

This is of similar size and appearance to Sisyplues goryi, Har., and like it cluthed with rusty coarse setre and earthy matter; indeed it is in all respects extremely like that species, differing only in the rather longer legs, the elytra a little more rounded at the sides and less tapered behind, the very sharp inner clypeal teeth, and feebler outer ones.

The sexual differences are slight in these and the small species of Sisyphus generally, and the synonymy of these still remains in the greatest confusion. Mr. Peringuey considers S. goryi, Har., to be identical with S. crispatus, Gory; but the first is described from TVest and the second from South Africa, and as a species exists in Senegambia to which the description of S. goryi can be applied there seems no reason to adopt Mr. Péringuey's view. The latter's species, S. nanniscus, is the insect called S. rugosus by Roth (a pre-occupied name) and considered by Gemminger and Harold to be the S. ocellatus of Reiche. The last appears to me to be another species of which there are representatives in the British Museum from Nyasaland and the interior of Angola. It is peculiar in having denuded spots upon the pronotum, as shown in Reiche's figure. These names should accordingly stand as follows:-
crispatus, Gory.
Abyssinia to Cape Culony. goryi, Péring. (nec Harold).
hirtus, Wiedem.
nanniscus, Péring.
rugosus, Roth (nec Gory).
ocellatus, Gemm. \& Har. (nec Reiche).
ocellatus, Reiche.
E. Africa.

## Onitis gazanus, sp. n.

Bresis, convexus, niger, subopacus, capite prothoraceque rage viridibus vel cæruleis; clypeo crebre punctato, carina frontali arcuata, integra, tuberculoque postico; pronoto rugose et dense punctato, postice medio immarginato, anguste bifoveolato; elytris striatis, interstitiis courexis, minute sat dense punctatis; metasterno fortiter punctato; femoribus omnibus inermibus, tibiis anticis quadridentatis:
$\delta$, tibiis anticis gracilihus, fortiter arcuatis, subtus breviter denticulatis; clypeo rugose punctato:
$\%$, clypeo transverse strigoso.
Long. $15-18 \mathrm{~mm}$. ; lat. max. $9 \cdot 5-11.5 \mathrm{~mm}$.

## Hab. E. Mashonaland: Chirinda Forest.

This was found in numbers by Mr. G. A. K. Marshall. It is a small compactly formed species allied to Onitis caffer, Bohem., but less shining and differently sculptured, with the femora quite unarmed in both sexes. It is black, with the head and prothorax sometimes faintly steel-blue, closely punctured and dull above, and moderately shining bencath. The head is closely punctured (the clypeus of the female transversely striated), with an arcuate and entire frontal carina and a slight frontal tubercle. The pronotum is densely and rugosely punctured, with the marginal line not complete behind and the basal foveæ elongate and rather close together. The elytra are striated, with the intervals convex and finely punctured.

## Melolonthidæ.

Apogonice (subgenus Rhynchogonite) minimn, sp. n.
Rufo-castanea, modice elongata, capite sat punctato, clypeo triangulari, acutissimo; prothorace fortiter punctato, marginibus antico et postico fere parallelis, lateribus antice rectis, angulis posticis arcuatis; elytris crebre fortiter punctatis, punctis partim
longitudinaliter ordinatis; pygidio grosse punctato, punctis piliferis.
Long. 5 mm . ; lat. max. 3 mm .

## Hab. S.E. Congo Free State: Katanga.

This is the smallest species of Apogonia known to me. It is exceedingly like A. acuminata, Arrow, but smaller and rather more numerously punctured and the clypens is still more sharply pointed. The pronotum is more strongly punctured, the front and hind margins are rather more parallel, and the sides appear straighter as seen from above and less convergent towards the front. The pygidium is also rather more punctured. The sexes are alike, except in the dilatation of the front and middle tarsi of the male.

## Cetoniidæ.

## Eccoptocnemis mashunus, sp. n.

Lete riridis vel craneo-viridis, nitidus, tarsis cyaneis, tibiis posticis atque intermediis intus flavo-pilosis ; capite crebre sat grosse punctato, antice leviter emarginato: prothorace lato, lateribus postice ralde divergentibus, sat fortiter punctato, medio fere læri; scutello rix punctato; elytris leeribus, punctis nonnullis minutissimis sparsutis; pygidio transrerse strigoso; corpore subtus medio toto læri, lateribus paulo punctatis, processu mesosternali circulari.
J. Pedibus posticis crassatis, tibiis dense flaro-setosis, pygidio minus strigoso.
Long. 24-31 mm. ; lat. max. $10 \cdot 5-14 \mathrm{~mm}$.

## Hab. Mashonaland.

'This species figures in Mr. Péringuey's 'Catalogue of the South-A frican Coleoptera' under the name of the WestAfican E. barthi, Harold, to which it is closely related. It agrees with it in the finge of yellow velvety hairs at the inside of the middle and hind tibio, very thick in the male, bat differs in the more shining and very feebly punctured elytra and the relatively shorter and rather differently shaped pronotum, the sides of which are less angulated at the middle, so that they are more divergent behind, and the base relatively broader. The sternal process is more narrowed between the middle coxæ, and the mesosternal part of it almost circular in shape.

Capt. Moser has described as a variety of Ceratorrhina (Neptunides) polychra, Thoms., a form, manowensis, Moser, which is abundant at Chirinda, feeding upon pineapples. It presents marked and constant differences from Thomson's
species, and is not merely one of the many colour-varicties of it. Its brown coloration is peculiar and practicaliy invariable, and it is very distinctly more elongate than C. polychroa. The females are at once distinguishable by the curions prolongation of the tips of the elytra, and the males have the hind femora strongly curved.

## Leucocelis cobaltinus, sp. n.

Niger, nitidus, prothoracis lateribus anguste rufis elytrisque obscure ceruleis, corpore elongato, subtus parce setoso; capite dense punctato, clypeo angusto, leviter bifido ; prothorace leviter punctato, antice paulo densius, marginibus lateralibus medio angulatis, postice fere parallelis, angulis posticis distinetis, basi regulariter arcuata; elỵtris grosse seriato-punctatis, striis 2 rel 3 posticis ; pygidio irregulariter annulato-punctato ; metasterni medio parcissime punctato, processu sat lato, rotundato :
$\sigma^{*}$, abdomine sulus paulo excavats, segnento ultimo medio minute producto, tarsis posticis multo longioribus.
Long. 12-13.5 mm.; lat. max. 6-7 mm.

## Hab. E. Mashonaland: Chirinda Forest.

This is a rather large species, devoid of white spots, and black, with the exception of the elytra, which are indigo or cobalt-blue, and a narrow red lateral border upon each side of the pronotum.

## Leucocelis ichthyurus, sp. n.

Niger, nitidus, clypeo, antennis pygidioque læete rufis, maculis parris albis inconspicue ornato, quarum 2 prothoracis lateralibus, 2 subbasalibus, elytrorum fascia mediana interrupta transversa punctisque nonnullis posticis; capite toto crebre punctato, clrpeo antice leriter inciso ; prothorace fortiter punctato, medio leviore, lateribus strigosis, basi omnino regulariter curratn, marginibus lateralibus postice paulo divergentibus, angulis posticis distinctis; elgtris fortiter seriato-punctatis, postice distincte striatis, ad suturam spinose productis; pygidio opaco, parce punctato; corpore subtus sat griseo-setoso, processu sternali lato, parum producto:
ס̃, tibire postice calcare interno gracilissimo, currato.
of prygidio medio late sulcato, fere bicuspidato, segmento rentrali ultimo postice late fulvo-ciliato.
Long. $10-11.5 \mathrm{~mm}$.; lat. max. $5-5.5 \mathrm{~mm}$.

## Mah. Mashonaland : Salisbury, Chirinda Forest.

I have seen a considerable number of specimens of this. It is very nearly related to L. rubriceps, Raffray, and may possibly prove to be a local race of it. It is a little larger Ann. \& Mag. N. Hist. Ser. 8. Vol. iii.
and much more scantily spotted with white, the spots being always extremely small and not infrequently absent altugether. 'The antenne, hearl, and pygidium are red, but not the last rentral segment, and the proilium is not spotted with white, whereas in our specimen of L. rubriceps there are four marginal spots. The body is a little longer and less sharply narrowed behind, and the strix on the posterior part of the elytra are less crowded.

In both these species the inner spur of the hind tibia is as long as the first two joints of the tarsus.

Mr. Péringuey has tran-ferred $L$, rubriceps to the gemus IIansoleopsis, on account of the asymmetrical front claws of the male, thus disregarding not only the general form, but more important characters common to both sexes, e. g. the prominent terminal spiracles of Mausoleopsis. It appears to me highly inadrisable to base any genus upon a feature found only in one sex.

## Leucocelis opacipennis, sp. n.

AEnea rel cuprea, nitida, elytris riridi-testaceis, opacis, prgidin, pedilus, corpore subtus prothoracisque lateribus grisen-setosis. punctis prothoracis utrinque 3 , elytrorum marginis externi postice 3-4 discique nonnullis minutis ; enrpore sat brevi : capite crebre punctato, antice fere bifido : prothorace ulique fortiter punctato, subcirculari, postice omnino arcuato, angulis nullis ; elytris antice et extus leviter punctatis, postice intus fortiter geminato-striatis; prgidio varioloso-1 unctato; mesosterno ris producto.
Long. $8 \cdot 5-9 \mathrm{~mm}$. ; lat. max. 5 mm .
Hub. Katanga: 150-200 miles W. of Kambove, 35004500 feet, 24 th Sept., 1907.

This is a species allied to L. spoliata, Har., which is referred by In. Kolbe to his subgenus Amaurina, but it differs from all the known species of that section in that the elytra only are opaque. It is of short form, with the prosnotum subcircular, very strongly punctured, the hind ansles obliterated, and the sides decorated with a borler of greyish hairs. There are six white spots forming two diverging straight lines upon the pronotum, three or four at the pasterior part of the outer margin of each elytron, and usually a few very minute ones upon the disk. The prgidium and lower surface are fairly well clothed with grey hair, and there are sometimes four basal patches of scales upon the former.

The sexes seem almost identical.

## Erotylidæ.

## Platydacne ferruginea, sp. n.

Ferruginea, hand nitida, antennis, prothoracis et elytrorum marginibus externis, horumque lineis 4 longitudinalibus apice haud conjunctis nigris; corpore supra toto sat dense et minuto punctato, prothorace lato, haseos lateribus sinuatis, angulis posticis acutis, marginibus lateralibus punctatis, haud crassis, regularitor areuatis; elytris conrexis, postice acuminatis, fortiter punctato-striatis, interstitiis modice convexis, orebre punctulatis.
Long. 14-17 mm.; lat. max. 6-7 mm.
Hab. N.E. Rhodesia: Serenje District; Katanga: Kambove, Lufira River.
$l^{\prime}$. fermginea is very closely allied to the typical speciez of the genus, $P$. villchata, Fairm., but rather narrower in shape, with the ground-colour rusty brown instead of red. The whole surface is very fincly and rather closely punctured, and the elytra are more depply striate-punctate. Each elytron has the extreme outer edge and four narrow longitudinal lines black, the outermost lme extending almost to the suture but not uniting with the others, which also remain distinct at their extremities.

## Platydacne levistriata, sp. n.

Subopaca, nigra, singulo elytro lineis rufis duabus ante apicem conjunctis, plerumque ante medium haud apparentibus, interdun etiam linea intermedia restigiali antica ornato; corpore vix punctato, prothorace quam longitudinem vix latiore, lateribus ad basin paulo divergentibus, postice fere rectis, basi regulariter arcuato, angulis posticis acutis; elytris postice acuminatis, lærissime striatis, haud punctatis, interstitiis paulo convexis; antennis gracilibus, haud late clavatis.
Long. 15-17 mm. ; lat. max. 6-7 mm.
Hab. S.E. Congo Free State: 150-200 miles W. of Kambove.

This is very near $P$. rufovittata, Har. (described as a species of Megaloducne). It is rather more oval in shape and more pointed behind, the sides of the prothorax are more divergent behind and the hind angles sharper, and the elytra are very lightly striated, without visible punctures in the strix or between them.
LXIX.-New Species and Varieties of $I_{y}$ droida Thecatr from the Andaman Islands. By James Ritchie, M.A., B.Sc., Natural History Department, the Royal Scottish Museum.
In a collection of IHydroids kindly entrusted to me for identification by Dr. Nelson Aumandale, Superintendent of the Indian Museum, there were contained such specimens as had been dredged in the deeper waters of the Indian Ocean. Of the twenty-four distinet forms in this collection I regard four as new species and two as undescribed varieties. Fuller descriptions of these, with figures, will be published, alongs with the report on the rest of the collection, in an early number of the 'Records of the Indian MIuseum,' the olject of ' the present notice being merely to chronicle the occurrence of a few interesting undescribel additions to the little-known deep-water Hydroid fauna of Indian seas.

## Campanularidæ.

## Hebella crateroides, sp. n.

Trophosome.-Colony epizoic, with a creeping hydrorhizal tube, which meanders over the stems and branches of other Hydroids. The hydrothece, which arise at irregular intervals from the stolon, are small and coloulless, like a wine-glass in shape, with firm walls marked in some cases by exceedingly faint corrugations, and gracefully everted round the margin. As the hydrotheca gradually diminishes in diameter from the margin almost uatil the hydrorhizal tube is reached, the hydranthophore is not distinctly indicated; and the hydrotheca cavity is separated from the common cavity of the colony only by a delicate film. The hydranth bears from about 6 to 8 tentacles.

Gonosome.-'The gonangia, which are borne on short indefinite stalks, are at least three times as large as the hydrothece. They are roughly cylindrical in shape and have irregularly corrugated walls, with an everted margin. Three medusæ, as a rule, develop from each blastostyle. The manubrium is large and four stout tentacles are present ere the medusa is set free.

This species is closely related to Hebella calcarala (A. Agassiz), from which it may be distinguished by the much smaller number of tentacles possessed by its hydranth and by the inverted-cone shape of its hydrotheca.

Loc. Gıowing; on Lyfocarpus phomiceus (Busk), dre fed 8 miles west of Interview Island, Andaman:. Depth 27045 fathoms.

## Sertularidæ.

Sertularella polyzonicts (Linn.), var. cornute, nov.
7rophosome.-Stem more definite than in var. gracilis of Bitish waters and branches more regular in their alternate origin. The facies of the trophosome on the whole approaches that of var. robusta, Kircheupauer, from the Cape of Good Hоре.

Gonosome. - While the gonangia have the elongate-ovate shape and the strongly marked corrugations of typical specimens, they are sumbounted by four stout spines lying crosswise in a plane at right angles to the long axis of the grnangium. 'To this character is clue the designation of the variety.

Loc. (a) Audaman Islands. Depth 490 fathoms.
(b) 8 miles west of Interview Island, Andamans. Depth 270-45 fathoms.

## Diphasia thornelyi, sp. n.

Trophosome.-Colony delicate, unbranched, with a nonfa*icled stem, which springs from a creeping stolon. The stems show no signs of nodes, but bear hydrotheca from the base upwards. The hydrothecr are biserial, both rows lying in the same plane, but they vary much in their position relative to one another, for although in most cases they are alternate or subalternate, on occasion an opposite arrangement is simulated. A hydrotheca is deep and narrow, with the inner edge adnate to the stem for practically its whole length, with the exception of a short, horizontal, knobbed ledge upon which the adcauline operculum is hinged. A short upturned intrathecal septum projects into the hydrotheca cavity from the middle of the abcauline wall, which beneath this point becomes much thicker. The distal part of the hydrotheca resembles a bracket projecting from the stem. The margin is smooth and rimmed, in shape arc-like, the curve of the arc bending outwards, and the aperture is tilted somewhat towards the stem. The partition separating hydrotheca cavity from stem cavity lies almost parallel to $t$ te abcauline wall, and terminates in a thickened ridge.

Gonosome.-Stalkless gonothece arise from close below
the hydrothece. They are ovate in shape, with a bulgine shoulder, a short neck, and a circular aperture. The distal half is ornamented with prominent scattered spines.

Loc. Andaman Islands. Collected by J. Wood-Mason.

## Plumularidæ.

## Aglaophenia septata, sp. n.

Trophosome.-Stem fascicled anl mubranched, it mm. high. The hydroclates are bome on the anteion tub) of the fascecle, whichalone is divided by faint moles into resular internodes. The lydroclades are biserial, lie on the anterime surface of the stem, from which they project at an angle of $4)^{2}-45^{\circ}$, and reach a maximum of 11 mm . in length. Kegularly placed notes occar on the hydroclades, the internoles heing divided by numerous strondy develomel septa, four of Which project from the posterior wall of the hydrohbeca, while three arise from the anterion wall of the intmande proximal to the hydrotheca. Ol these one traverses the base of the mesial sarcotheca.

The hydrothece are rather distant, very narow at the base, but wilaning greatly towards the trp, almon obemical. The anterior profile is straight but for a concavity oppesite the tnp of the mesial sareatheca. The margin is hmizomtal and has a pominent anterion tooth, flanked on each il ly fiur distinct sinnations. There is no intrathecal rilge, buit the posterior wall bends inwarls just above the base of the liydrotheca. The suracal? cine sarcotheca slightly overtop the margin of the hydrotheca. They are large and cylindrical and possess an internal septum. The mesial saticotheea is about two-fifths the length of the hydrotheca, to which it is altegether aninate excepit for a free sjout-like tip. A lutton of clitin projects into its cavity from the wall of the hydrotheca, proximal to the point where it becomes fiee.

Of cauline sarcothecæ, one lies on the anterior of the stem, proximal to the hydrochate-bearing mocess, another lies on the immer side of the proces-bonth of these haing large and similar to the mesial sarcotheca,-while a thime, a mere perforation, lies on the anterior of the process itself.

Gonesme.-A kind of corbula, entangled amonst fibres at the base of the colon!y, I assume to have belorged in the colmiy. It is of peculiartye. A erlimer, formed of delinate phates of chitin, contains five splerial rymoluctive bodien, and along each side run two rows of projecting leaves. Each of the lower rows contains about 9 tube-like leares,
furaished with small sarcothecre arranged biserially. Each of the upper rows has 10 broader leaves, often contortei, ami also bearing sarcothece irregularly arranged along the margins. The structure seems to resemble a type of open corbula whera, instead of the leaves curling inwards to motect the reproductive bodies, special delicate chitimons wings have arisen between the leaves, these encousing the gonangia in a cylinder.

Loc. Andaman Islands. Depth 490 fithoms.

## Lytocarpus annandalei, sp. n.

Tirphosome.-Culony dark brown in colour, unbranched, with a fascicled stem traverscd here and there by pale-colouret? constrictions slanting firom behind downwards and forwards. 'The anterior tu'se, which is not divided into nodes, alone bears hydrelades, and these are cluse set and alternate, and are divided into regular hydrotheca-bariag internodes. The hydrothecee are clusely approximated, deep, and rodely ovate in outline, with an aperture facing outwards from the stem at an angle of about $45^{\circ}$. The lower hath oi their profite is convex, the upper concave, white the margin bears a single promin ant anterior tooth, flanked by four sinuations on each side. The mesial sarcotheca is very broad, adnate for more than half the height of the hydrotheea, but with a free spout-like extremity; the supra-calycine sarcothecæ are also very large, reach just above the margin of the hydrotheca, and posess a huge aperture. They are cylindrical in shape, the cylinder being broken by a constriction about midwar, which is assuchated with an internal rilge traversing: part of their cavity from the posterior wall.

The intrathecal ridge is little evilent, but it projects into the lamen of the hydrutheea from a knob of chitin tarminating an angular inbending of the posterior wall near the floor of the cavity. The bases of the two sides of the angle are marked by well-lefined ridges projecting into the cavity of the internode, while a third ridge arises just above the bases of the supra-calycine nematophores. A shortre internolal finge arises from the proximal porion of the anterior wall. I'wo characteristic ridges are associated with the mesial nematophore: a knob of chitin prejects into the nematophore cavity from the hydrotheca wall, while a simous septum traverses the base of the nematophore cavity.
'Two large, scoop-shaped, cauline sarcothecæ lie at the hase of each hydroctade, and on the anterior of the hydro-clade-baring process is a small tubular sarcotheca.

Gonosome.-A few structures, apparently phylactncarps, replace hydroclades towards the hase of the stem. They are ivided into regular internodes each with three nematophores, two lateral and one median and proximal. Unfortumately no gonangia are present. These structures are readily seen to be morphologically equivalent to hydroclades.

Loc. 'Investigator,' Station 2.t1, lat. $10^{\circ} 12^{\prime}$ N., long. $92^{\circ} 20^{\prime} 30^{\prime \prime}$ E., between the Andaman and Nicoljar Islands. Depth 606 fathoms.

## Hulicornaria hians, Busk, var. profunda, nov.

Trophosome. - Considerable variations are exhibited by the trophosome, but these seem in the main to bo due to differences in age. The thecate internonles, white they are twice as broad as long at the bese of a hydroclade, gradually lengthen till at the distal end their length may be to their breadth as four to one. The mesial sarcotheca in mature colonies is ardnate almost to the lip of the hydrotheca, projecting beyond the margin as a shont free spout; in young colonies it does not reach even to the intrathecal ridge, and at this stage closely resembles that of young colonies of II. curiabilis, Nutting *. In all stages, however, its anterin profile is concave, a character which distinguishes this species from M. Zalei (Marktanner-Turneretscher).

The trophosome of this variety is distinguished from that described and figured by Bale $\dagger$ liy the greater length of the thecate internodes compared with their diameter, the greater depth and more erect posture of the hydrothecæ, and the greater distance which separates the intrathecal septum from the base of the bydrotheca. The less prominent nature of the marginal tecth and the small size of the colonies ( 4 cm .) are variations of little significance.

Goncsome.-The gonangia, which have not hitherto been described, are quite unprotected and are home on very short stalk k , one at the base of each hydroclade. In shape they are saucer-like, convex beneath, concave above, appearing as perfect disks, up to 0.38 mm . in diameter, when viewed from the anterior of the colony.

Loc. Andamans, 1899.

[^67]
## LXX.-A new Specific Name for an Orectolubid Shark.

 By C. 'Tate Regan, M.A.(Published by permission of the Trustees of the British Museum.)
I have just received a copy of "A Revision of the Australian Orectolobidæ," by J. Douglas Ogilby and A. R. McCulloch (Journ. \& Proc. R. Soc. N. S. Wales, xlii. 1908). In this the authors describe and figure under the name Orectolobus clusypogon, Bleek., a shark, from Torres Straits, which appears to be distinct from that species, the type of which, from Waigiou, is in the British Museum. I therefore propose for this new form the name Orectololus ogillyi, in honour of the Australian ichthyologist who has studied this group of sharks.

The main differences between the two species may be shown thas:-

## Orectolobus ogilbyi.

Gill-openings decreasing in size from the first to the fourth; last larger; last two closer together than the rest.

Fringes on each side of the head in three separate groups.

Origin of first dorsal fin well hehind the middle of the total length.
Distance between origins of dorsals nearly $\frac{1}{2}$ that from origin of second dorsal to end of tail.

## O. dasypogon.

Firstgill-openingslightly smaller than the rest, which are of equal size and equidistant.

Fringes on each side of the head in two groups, the more posterior equivalent to the last two in $O$. ogilbyi.

Origin of first dorsal fin in the middle of the total length.

Distance between origins of dorsals slightly more than $\frac{1}{3}$ that from origin of second dorsal to end of tail.
O. ogilbyi is certainly very closely allied to $O$. dasypogon, and the two species can scarcely be placed in different genera. The genus Eucrossortinus, established by me for O. dasypogon, chiefly on account of the form of the gill-openings, becomes a synonym of Orectolobus.

## BIBLIOGRAPHICAL NOTICES.

Guide to the Whates, Porpoises, and Dolphiins (Order Cetacea) eikhited in the Depurtment of Zoolury, British 1luseum (Natural History). Illustrated by 33 Figures. London: Printed by Order of the Trustees, 1909. Price $4 d$.
The (inide-Books to the Zoological Department of the Natural History Mrseum have been steadily growing, both in size and number, fror years past, so that they now proside a fairly complete
surver of the animal kinghom. In their entirety it might justly be claimed for them that they form one of the most popular texthooks of zoolory which has ever appeare l. Thus they differ from most other books of their kind, which are of liftle nse sare as a source of reference to the actual specimens exhibited.

In the Guide to the Whale-Room of the Museum Mr. I fideklitr has, in a surprisingly small space, contrived to pack an amazing amount of information concerning these creatures, the most highly specialized of all the Manmalia. Though most of the facts here given hare fond their way long since into the majority of popular matural history books, much is here incladed that will be new in the general reader, as, for example, the fact that certain of the whales, motably the Indim Porpoise, have " minute scales emberded in the skin of part of the back; and these surget that whales are derived from animals furnished with a comple to hony armour." We shouk have profersed the term "hony nedules" in place of "scales": the mature of these would pernaps lave heon hrought home to the reater the more forcihly if it had hen puintel out that they were comparable to the bony phates cosering the back of the armadillo.

The shont areount of the extinct Cectareans is admirable, and adds inmensely to the value of this mont womerful summary of a group of amimals of which lithe is known ly the ecmesal publie.

The illustratinas have evidently been selected with the greatest care and are singularly well reproduced.

 (Witured Mistory). Illu-trated hy 16 Vigures. Lemdon: Printed by Order of the Trustees, 1903. Price 4 d.
Mr. Tmmments (inide to the Anthopmogical Conlertion is an extremely uscful piece of work. The formation and arrangement of this collection, it should lie remembered, was entirely camien out by Mr. Lydekker. In the near future we hope to see this collection still further enlarged, for in this particular we are behind our neighbours the Germans. But to return to the Cuide. In the preparation of this the Author was confronted with a difficult task, for a guide-book must of necessity be hrief, and it could have heen no easy matter to condense eren the main outlines of anthropology in so small a space. The classitication of the races of matkind is a thorny sulpeet, and from its general unfamiliarity an exceedingly difficult subject to present in a prpular form ; and the Author has certainly come rell out of the ordeal.

There is only one slip to which we would direct attentiou, and this concerns the Bisharis, which on p. 11 are placed in the Semitic group and on p. 12 are included in the Hamitic group, being described as the purest East-Lfrican representatives thereof.

The illustrations, as in the Guide just moticed, are excellent.

Preston.

## INDEX to VOL. III.

Abants, characterg of the new genus, 493.

Abulfeda, characters of the new genus, 495.
Acerodon, notes on the genus, 20 ; new species of, 25.
Aclatina, new species of, 182.
Adauctus, claracters of the new genus, 492.
Adelium, new species of, 411.
$\Lambda$ dolopus, new species of, 223 .
Acrocera, new species of, 434 .
Athalotus, new species of, 318.
Aglaophenia, new species of, 526 .
Agunga, new species of, 334 .
Alcyonarians from the Gulf of Cutch, on, 362.
Amallophora, new species of, 124.
Andersen, K., on the genus Acerodon, 20; on the charactersand afinities of Desmalopex and I'teralopex, 213 ; on a new species of J'teropus from the Loyalty Islands, 233; on new bats from the Solomon Islands, 266.

Andrems, Dr. C. W., on mem steneosaturs from the Oxford clay of l'eterborough, 299, 384.
Angitia, new species of, 4 统.
Anomalurus, new species of, 301 .
Anthobosca, new species of, 482.
Aphanus, new species of, 236.
A pocaucus, characters of the new genus, 506.
Apogonia, new species of, 519.
Arber, E. A. N., on the fossil plants of the Kent coalfield, 87 .
Arctomys, new species of, 259.
Arcyothora, new species of, 481.
Ariphron, new species of, 130.
Arrow, G. J., on new coleoptera from Rhodesia, 517.
Asilis, new species of, 401.
Aspilocoryphus, new species of, 32 C .
Astrommicea, nerr species of, 361.
A thinsonianus, characters of the new ernule, :3.43.

Atlantoxerus; note on the genus; 473.

Austen, E. E., on new African phlebotomic diptera, 280; on new blood-sucking Muscide, 285.
Automolis, new species of, 458 .
Avernus, new species nf, 188.
Bacalipalpus, nerv species of, 41t.
Bather, F. A., on Eocidaris and some species referred to it, 43 ; on the type of Cidaris, 88.
Blelinlarynx, characters of the new genus, 290.
Bethune-Baker, Gr. T., on nevp African lepidoptera, 42 .
Biugham, Lt.-Col. C. T., on two new Mutillidæ from Queensland, 436.

Bitoma, new species of, 385.
Bombilioder, new species of, 457.
Books, new:-Catalogne of the Lepidoptera Phalrene in the Britisls Museum, vol. vii., 382 ; Smith's Naturalist in Tasmania, 456 ; Guide to the Whales, Porpoises, and Dolphins in the British Muscum, 529 ; Guide to the specimaens of the laces of Mankind in the British Museum, 530.
Boomslang, on the toxic action of the bite of the, 271 .
Borolia, new species of, 430 .
Boulenger, G. A., on a new gobiid fish from the Niger, 42.
Brachioteuthis, new species of, 449.

Brown, Najor T., on new NewZealand coleoptera, 223, 335.
Bulimulus, new species of, 5l0.
Bulimus, new species of, 509 .
Burr, M., notes on forficularia, 249, 253.

Byrne, L. W., on fishes from the Irish slope, 279.
Calletæra, new species of, 9 .
Callidula, new species of, 94.
Callistoplepa, new species of, 183.
Calliteuthis, new species of, 155.

Calman, $\mathrm{D}_{3}$. W, T., on a new cab from the Indian Ocean, 30 ; on the genus Puerulus and the post-larval development of the spiny lobsters, 441.

Calocarcinus, characters of the new genus, 30.
Calphurnia, characters of the new grenus, 502.
Calymniodes, new species of, 459 .
Capnodes, now species of, 432.
Celænorhinus, new species of, 89 .
(ephalopoda, new, 446.
Cercaria, new species of, 2:38.
Chalenata, new species of, 461.
Chalinolobus, new species of, 150 .
Char, on the, of Great Britain, 111.
Chauliops, new species of, $3: 8$.
Chorops, note on the generic name, 315.

Choleva, new species of, 230 .
Chubb, E. C., on mammals from the Upper Zambezi River, 33.
Cichlosoma, new species of, 234 .
Cidaris, on the type of, 83 .
Cilibe, nerr species of, 408.
Cladocarpus plumosus, note on, 310 .
Clark, A. II., on the genus Encrinus, 308.

Clark, Prof. II. L., on the type of Cidaris, 88.
Cleis, new species of, 95 .
(Ooleoptera, new, 223, 385, 517.
Colgan, N., ol locomotion and the use of slime-threads in the marine mollusca, 354.
Consivius, characters of the new genus, 320.
Correbia, new species of, 458 .
Coxelus, new species of, 386.

Dollman, $G$., on mammals from Katanga, 348.
Doxozilora, characters of the now genus, 412.
Druce, H., on new heterocera from Tropical S. America, 345, 457; on new heterncera from Dutch New Guinea, 347.
Druce, H. H., on a new hesperid from l'eru, 438.
Eccoptocnemis, new species of, 520 .
Ectropis, new species of, 93.
Elaphrodes, characters of the new genus, 423.
Elaphroptera, new species of, 134.
Eleotris, new species of, 42 .
Ellobius, new species of, 205.
Elops, rerision of the genus, 37 ; new species of, 38 .
Elymas, characters of the new genus, 504.

Emarginea, new species of, 346 .
Encrinus, note on the genus, 308.
Entomostraca, on Scottish, 122.
Eocidaris, note on the genus, 43.
Ephutomorpha, new species of, 487.
Epibomius, characters of the new genus, 328.
Epiphragmophora, new species of, 508.

Epixerus, characters of the uew genus, 472.
Erastrioides, new species of, 463.
Ercheia, new species of, 431.
Eremocoris, new species of, 494.
Esmun, characters of the new genus, 330.

Esphalmeninæ, characters of the new subfamily, 250 .
Esphalmenus, characters of the new genus, 251.
Estigmene, new species of, 429.
Eublemma, new species of, 462.
Euconchœcia, new species of, 128.
Eucusmetus, new species of, 332.
Euhemerus, characiers of the new genus, 331 .
Euproctis, new species of, 428 .

Euscopus, new species of, 496.
Eusoma, new species of, 397.
Euxerus, characters of the new genus, 473.
Evotomys, new subspecies of, 419.
Exocoetus exiliens, on the type of, 147.

Fischeria, new species of, 186.
Fishes, new, 38, 42, 115, 234, 270, 279,529 ; on the anatomy and classification of the scombroid, 66 ; on the classification of teleostean, 75.

Fitz-Simons, F. W., on the toxic action of the bite of the boomslang, 271.

Forficularia, notes on, 249, 253.
Funisciurus, note on the genus, 471.
Gadus luscus, on a young stage of, 153.

Gardena, new species of, 505.
Gardiner, C. I., on the sedimentary rocks of the Tourmakeady district, 235.

Gargetta, new species of, 424.
Gathocles, new species of, 388.
Geological Society, proceedings of the, $87,235,315,383$.
Georychus, new species of, 35.
Geosciurus, note on the genus, 473.
Geroda, new species of, 460.
Gibbus, new species of, 180.
Glandina, new species of, 507 .
Glossopelta, new species of, 496.
Glyphodes, new species of, 437.
Gonodes, new species of, 346 .
Gonsalvus, new species of, 314.
Griffini, Dr. A., on new species of Gryllacris, 366.
Gryllacris, new species of, 366 .
Grynoma, new species of, 231.
Guinther, Dr. A., on the type of Exocœtus exiliens (L. Gmel.), 147.

Hrmatobia, new species of, 288.
Halicornaria hians, new variety of, 528.

Hasora, new species of, 91.
Hebrus, new species of, 497.
Hebella, new species of, 524 .
Helicarion, new species of, 181.
Heliosciurus, note on the genus, 470.

Heterogramma, new species of, 270.
Heteroptera, new, 40, 317, 491.
Hilda, new species of, 41.
Hipposiderus, new species of, 268 .

Holt, E. TV. L., on fishes from the Irish slope, 279.
Homarus vulgaris, on a case of abnormal oviducts in, 1.
Homoptera, new, 41, 187.
Homorus, new species of, 186.
Hyblæa, new species of, 96 .
Hyboscarta, new species of, 190.
Hydroid, note on a rare plumularian, 310.

Hydroida Thecata from the Andaman Islands, 524.
Hymenoptera, new, 131, 476, 486.
Hypena, new species of, 483.
Hyperomma, new species of, 227.
Hypochrosis, new species of, 92.
Hypothripa, new species of, 430.
Idalus, new species of, 458.
Induna, new species of, 94 .
Ischnodemus, new species of, 326.
Ischnorhina, new species of, 191.
Iswara, note on the genus, 476 .
Kanaima, characters of the new genus, 212.

Kendall, Rev. H. G. O., on palæolithic implements from Hackpen Hill, 383.

Kinbergella, characters of the new genus, 177.
Korobona, characters of the new genus, 209.
Lielia, new species of, 428.
Langucys, new species of, 345.
Laomys, characters of the new genus, 373.

Leipaxais, new species of, 428.
Leistera, characters of the new genus, 96.
Lemonia taraxaci, new subspecies of, 7.

Lepasta, new species of, 466 .
Lepidoptera, new, 7, 89, 100, 345, $347,422,438,457$; on the, collected by W. J. Burchell in Brazil, 7, 98.
Leucncelis, new species of, 521, 522.
Lewisiella, characters of the new genus, 398.
Longstaff, Mrs., on the genus Loxonema, 315.
Lophochlora, new species of, 94.
Loxotephria, new species of, 93 .
Lua, characters of the new genus, 342.

Lygæus, new species of, $31 \Omega$.
Lyperosia, new species of, 285.
Lytocarpus, new species of, 527.

Macaca, new species of, 380 .
M'Jntosh, Prof., on a young stage of Gadus luscus, 153 ; on the British Spionidx, 156 ; on the Spionide collected by H.M.S. ' Porcupine,' 175.
Macronoctua, new species of, 459.
Macropes, new species of, 323 .
Mahanarva, characters of the new genus, 210.
Makonaima, characters of the new genis, $20 \mathrm{u}^{2}$.
Manmals, new, 25, 3.5, 13.0, 23.3, $246,257,266,351,37-2,374,378$, $380,415,439,514$.
Manatanus, characters of the new genus, 494.
Maramaldus, characters of the new genus, 333.
Marmosa, new species of, 379 .
Marshalliana, new species of, 425.
Meragisa, new species of, 467.
Meriones, new species of, 262.
Merragata, new species of, 498.
Mesembriomys, note on the genus, 372.

- argurus, new subspecies of, 1.7.

Metarbela, new species of, 425.
Metaxina, characters of the new genus, 407.
Metopolophota, characters of the new genus, 424.
Mezira, new species of, 497.
Microtus, new species of, $263,420$.
Microvelia, new species of, 499 .
Mictochroa, new species of, 460.
Niller, G. S., on new European mammals, 415.
Miocidaris, note on the genus, 62.
Miresa, new species of, 426.
Miselia, new species of, 345.
Mollusca, new, 180, 314, 446, 507; on locomotion and the use of slime-threads in the marine, 3 อ 4.
Moschites, new species of, 453.
Moulton, J. C., on the rhopalocera collected by W. J. Burchell in Brazil, 7, 98.
Mungos sanguineus, new subspecies of, 514.
Mus, nevs subspecies of, 421, 441.
Muscidæ, new blood-sucking, 285.
Mutilla, news species of, 486.
Mycetopus, new species of, 513.
Myosciurns, characters of the new genus, 474.

Myrsilus, characters of the new grenus, 470.
Myzine, new species of, 476 .
Nadata, new species of, 347.
Napata, new species of, 457.
Narosa, new species of, 426 .
Nassa, new species of, 512.
Naudarensia, new species of, 339.
Negla, new species of, 435.
Neoavernus, characters of the new genus, 189.
Neolethieus, characters of the new greuts, 340 .
Neomonecphora, characters of the new genus, 206.
Neosphenorhina, claracters of the new genus, 205.
Nerine, remarks on species of, 150.
Nerinides, new species of, $17 \%$.
Nerthus, characters of the new genus, 327.
Nicoll, Dr. W., notes on larval trematodes, 237.
Nysius, new species of, 321.
Oberonia, new species of, 422 .
Odontria, new species of, 400 .
Ecomys, new species of, 378.
Ogilby, J. D., on the generic name Cherops, 315.
Ogovia, new species of, 431.
Olapa, new species of, 428.
Omalium, new species of, 228.
Onitis, new species of, 519.
Opharus, new species of, 459 .
Ophiusa, new species of, 97,432 .
Opisthoplatys, new species of, 506.
Orectolobus, new species of, 529.
Ormiscodes, new species of, 465 .
Orthalicus powissianus, new variety of, 512 .
Orthoptera, nerr, 366.
Otocinclus, new species of, 231.
Paguma, new species of, 377 .
Palinuridæ, on the post-larral development of the, 441.
Paludestrina, new species of, 513.
Pamera, new species of, 491.
Pamerana, characters of the new genus, 331.
Paracodia, new species of, 465.
Paradoxurus, new species of, 374.
Parangitia, new species of, 463.
Paraphanta, new species of, 427.
Parasa, new species of, 426 .
Paraxerus, note on the genus, 471.
515. cepapi, new subspecies of, 515.

Pamara, new species of, 90.
’edilophorus, new species of, 396 .
Permocidoris, note on the genus, 63.

Philematomyia, characters of the new genus, 295.
Phryganodes, new species of, 436.
Phyciodes, new species of, 100 .
Phymatopheea, new species of, 405.
Pilocrocis, new species of, 436 .
Pirkimerus, new species of, 322.
Pitymys, new species of, 420 .
Planorbis, new species of, 512 .
Platy dacne, new species of, 523 .
Plesia, new species of, 480.
Plcearia, new species of, 505.
Ploiariola, new species of, 501.
Poecilia, new species of, 235 .
Polydora, remarks on species of, 169.

Polypus, new species of, 446.
Pore ta, new species of, 465 .
Presbytis, new subspecies of, 439.
Preston, II. B., on new land and freshwater shells from Africa, 180; on new land, freshwater, and marine shells from S. America, 507.

Promanus, new species of, 232.
Protarphius, new species of, 389 .
Protopristus, characters of the new genus, 225.
Protoxerus, note on the genus, 472.

Pseudachatina, new species of, 183.
Pseudelaphroptera, new species of, 133.

Pseudoglessula, new species of, 185 .
Pseudotharybis, characters of the new genus, 126.
Pseudotrochus, new species of, 184.
Pteralopex, on the affinities of, 218; new species of, 266.
Pterocyclophora, new species of, 348.

Pteropus, new species of, 233.
Puerulus, note on the genus, 441.
Pycnomerus, new species of, 393.
Pygospio elegans, note on, 166.
Pyragra, new species of, 254.
Quedius, new species of, 226.
Regan, C. T., revision of the genus Elops, 37 ; on the anatomy and classification of the scombroid fishes, 66 ; on the classification of teleostean fishes, 75 ; on the char of Great Britain, 111; on new
freshwater fishes from South America, 23土; on a new cichlid fish from La Plata, 270; new specitic name for an Orectolobid shark, 529.
Reptiles, new, 300.
Reynolds, Prof. S. H., on the sedimeutary rocks of the Tourmakeady district, 235.
Rhanidophora, new species of, 435.
Rhinochimæra, new species of, 279.
Rhinosciurus, new species of, 440 .
Rhynchotal notes, 40, 187, 317.
Ricardo, Miss G., on new species of Tabanus from India and Assam, 487.

Ridewood, Dr. Wr. G., on a case of abnornal oxiducts in Homarus vulgaris, 1.
Ritchie, J., on a rare plumularian hydroid, 310; on new Hydroida Thecata from the Andaman Islands, 524.
Rossia, new species of, 454.
Rothschild, Hou. W., on a new Lemonia, 7.
Russell, E. S., on the cephalopoda collected by the 'Goldseeker,' 446.
Sadoletus, new species of, 329 .
Salvelinus, new species of, 115.
Sarmatia, new species of, 433 .
Sciurus, new species of, 418, 439 ; note on the African species of, 469.

Scolecolepis, remarks on species of, 160, 175.
Scolia, note on the genus, 483.
Scoliidæ, on some genera of the, 476.

Scombroid fishes, on the anatomy and classification of the, 66 .
Scopelodes, new species of, 95 .
Scott, T., on new and rare entomostraca, 122.
Selenopalpus, new species of, 413.
Sepiola, new species of, $4 \overline{5} 4$.
Sertularella polyzonias, new variety of, 525.
Shark, new specific name for an Orectolobid, 529.
Sisyphus, new species of, 517.
Small, W., notes on larval trematodes, 237.
Solaropsis, new species of, 508.
Soletellina, new species of, 314.
Soloe, new species of, 429 .
Sorex, new subspecies of, 415 .

Sowerby, G. B., ou a new species of Soletelliua, 314.
Sphodroscarta, new species of, 190.
Spio, on the British species of, 161 ; new species of, 165.
Spionidie, on the British, 156 ; on the, collected by H.M.S. ' Porcupine,' 175.
Spiophanes bombyx, note on, 167.
Squirrels, on the generic arrangement of the African, 467.
Stemmatophora, new species of, 436.

Steneosaurus, new species of, 300.
Stephanochasmus, notes on species of, 244.
Stomoxys, new species of, 292.
Stopes, Dr. M. C., on plant-containing nodules from Japan, 383.
Stygeromyia, new species of, 286 .
Subulina, new species of, 186 .
Sus, new species of, 441.
Siwnhae, Col. C., on new IndoMalayan and African lepidoptera, 89.

Sylepta, new species of, 437.
Symphysius, characters of the new genus, 391.
Synegia, new species of, 91 .
Synelis, new species of, 94.
T'abanus, new species of, 487.
Tachynomyia, new species of, 137.
'I'aondium, new spectes of, 451 .
T'arache, new species of, 462.
Tarachidia, new species of, 462.
Tatera, new species of, 249 .
Teleostei, on the classification of the, 75.
Telephoromyia, new species of, 131.
'Ieutates, enaracter's of the new genus, 335.
Thapsia, new species of, 181.
Thomas, O., on mammals from N.E. Kimberley, 149; on mammals
from Turkestan, 257; on the N. Australian species of Mesembriomys, 372 ; on new species of Paradoxurus and a new l'agum?, 374 ; on new species of Ecomys and Marmosa, 378; on two new macaques from W. Java, 380 ; on the generic arrangement of the African squirrels, 467.
Thomson, Prof. J. A., on alcyonarians from the Gulf of Cutch, 362.

Thynnidx, new species of, 131.
Thynnus, new species of, 138.
Timasius, characters of the new genus, 493.
Tiphia, note on the genus, 483.
Tomaspis, new species of, 193.
Tomaspisima, characters of the new genus, 206.
Trematodes, notes on larval, 237.
Triphyllus, new species of, 395 .
Turner, R. E., on new or littleknown species of Thynnidæ, 131; on some genera of the Scoliidr, 476.

Typhoctes, new species of, 485.
Uyana, characters of the new genus, 97.

Usilanus, characters of the new genus, 341.
Uzza, characters of the new genus, 338.

Valleriola, new species of, 40 .
Westermannia, new species of, 430.
Wroughton, R. C., on new species of Dendromus and Tatera, 246; on four new African mammals, 514.

Xanthocalanus, new species of, 122.
Xerus, note on the genus, 473.
Yanguna, new species of, 438.
Zyzomys, characters of the new genus, 372.

\section*{PLEASE DO NOT REMOVE CARDS OR SLIPS FROM THIS POCKET}```

[^0]:    * For structure of ras diferens, see Gmobhen, C... Arb. Zool. In-t. Wi-n, i. I-TE, pl. i. fig. 6 ; also Merrick, F. II.." The American Lobstor," Bull. U.S. Fish. Comm., Washington, 1895, pl. xxxri. fig. 120.
    $\dagger$ Inat. Anzeiger, lson, p. iju: : and Proc. Zonl. Suc, Lond. I!ol, i. p. 46 .

[^1]:    * Tle rance of the "subrenus" Acerachon is stated br Matsclie to be the: I'biliphiues, Gilolo, Datian, Cel-ibes, Flores, and Imor (Mesachir. p. O., leath, and essemtially the same distilution is given hy Miller
     from the known range of the fenus. The neonds af Acorchon from the Giluln eroup are based on mistaken identifications of Gimys l'terones comicope and his Pteropus muclioti var. butchicna; the latter name is a synonym of the former, and Fteropus caniceps a ferfectly trical I'teropus.

[^2]:    * Some of the differential characters of Acerodion given by Miller in
     1907) prove, on examination of a larger material of Pteropus and Acer, flon than that studied by Miller: to be matenable. "Lower inciours [Hiller writes] differing fiom those of Pheromes in the much greater comtrast in size betwe the imer and onter twoth of each pair." In - fereon .n $i_{2}$ is in cross-section of the crown from trice to three time- the pulk of $i_{1}$; practically the same is the case in a majurity of species of Pteropus, while in others (e, g. I't. Lombocensis, solitarius, samoènstis, anetiumus, pselaphon, prilosus, tuberculatus) the disproportion in the size of these teeth is greater than in any Accrodon, $i_{2}$ being sumetimes fur, five, or six times the bulk of $i_{1}$. "Caniues much shortened as compared with Pteropus, the mandibular canine little exceeding the heighlit of $\mathrm{pm}_{3}$." There is in Pteropus every intergradation from short, stont, and distinctly recurved, to very long, slender, and nearly strairht canines. "Though reduced in length the canimes retain their thickness, and the cingulum is even better developed than in the related genus." The numerous species of Pteropus show auy intermediate stage from a very narrow to an excessively broad cingulum of the canines (the latter extreme exhibited by Pt. sumoënsis, anetiumus, pseluphon, pilosus, tulerculatus, insularis, phiceocephalus); the cingulum of the canines is in these species of Pteropus much broader than in any Acerodon.
    † Index Gen. Mamm. p. 73 (1901).

[^3]:    * I have to thank Mr. B. B. Woodward and Mr. C. Davies Sherbom for having directed my attention to this periodical. It is not in the library of the Natural History Museum. I have seen a copy in the Bloomsbury Museum.
    $\dagger$ The chief character of Acerodon is pointed out by Jourdan in the
    
    
    
     voisines." From this there is no doubt whatever that the type of Acerodon is A.jubatus. But Jourdan makes also, in this connexion, some
    
    
    
    
    
    
     of two widely different spece-s, the trate $1 \%$ canihmonsis the slims desmibed by (fuoy et (iaimard), a rpecies clacly allied to It. tomymus, and I't. tuberculdus (the shall de chibmed by the -ame anthors and erro-
     which is allied to Pt. pselaphon. I't. vaniziorensis and tuberculutus are ispical members of the genus I'teropus.

[^4]:    * This stutment, that the "Comptes lienulu," if the merting of the
     aitor that date, misht seem to be contratheted by the leat that this
     timens for every dat of " jantior less." Bat " jansier l-is " is ohmouly
     which page the true table for Jan. 1838 appears.

[^5]:    Neasurements of two skulls only.

[^6]:    * I am indebted to Dr. N. Annandale, Superintendent of the Imlian Museum, Calcutta, for a specimen of this crab.
    $\dagger$ Gardiner's 'Fauna . . . Maldives,' i. p. 239 (1902).

[^7]:    - It is surprising that this note should thus far have prombed but a sincre protest. With that protest-made by Profussor J. W. (iregory (Feb., 190*)-I am in complete sympathy. Dr. (iregory says that I

[^8]:    * G. \& F. Sandbercer, 1855. The expression "Sandberger" is used throughout, to aroid cumbrous repetition.

[^9]:    * Fide R. Howse, 'Note on the Right of Priority' [1857].

[^10]:    * Epinmula, the most generalized Trichiuroid, is not represented in the Briti.h Museum. Dr. Th. (iill very kiudly examined the specimen of $E$. magistralis in the Smithsonian Institution and wrote to me, "the pelvic bones are attemuated forwards and terminate in a ligament connecting with the 'clavicles' at their symphysis." These words describe the condition I observe in Thyrsites, but on dissecting away the ligament in which the pelvic hones terminate I find that the latter extend forward, enclosed in a ligamentous sheath, to between the cleithra.

[^11]:    * The rery aberrant and highly specialized Lurarus is the onlr exception.

[^12]:    ** I am indebted to Dr. Gill for a radiograph of Épimunto, which shonw the vertebre to manber $31(15+16)$. In Thyrsites promethe us there an w 34 vertebræ.

[^13]:    - Owing to the contitery of Th. Fmith W icelrame I have incol able to rerify this character in I'alcorkynchus and Blochius.

[^14]:    * I have examined the trpe of Icichthys lo kingtomi. which is a specio. of Centrolophus.

[^15]:    * Cluriger, carrying a clul): referring to the cluls-like form of the left leg of fifth pair.

[^16]:    * "Teber Inalocypriden," Zoolugisch. Jahrb. Bd. r. p. 277, pl. xxviii. figs. 1-10 (1890).
    $\dagger$ Trans. Linn. Soc. vol. vi. p. 142, figs. 5, 6, 3?, 34, 38 (1894).
    $\ddagger$ Trans. Zool. Soc. vol. xri. p. 190, pl. xxii. figs. 9-15 (1902).

[^17]:    *Figures drawn with a "Zeiss" camera, and all enlarged.

[^18]:    * Liitken attached considerable taxonomic value to the presence of either one or tro simple rays in front of the first branched pectoral ray. If the additional simple ray is of some length and connected with the second simple ray by an interradial membrane, its presence, no doubt, forms a specitic character. However, I find that in several species, which were supposed to have, and are generally described as having, one simple ray only, there is a rudimentary additional ray present. It is more or less covered by the skiu, attached to the base of the long simple ray, with which in adult individuals it actually coalesces, thus increasing the power of resistance at the spot where it is most wanted for flying. I suppose that in toung individuals this ray is much more con-picuously. distinct.

[^19]:    * In Bleeker: figure of this species the rentral fins are represented much too short ; they were mutilated in the single specimen which he had and which is now in the British Museum.
    + I am indebted to Dr. Pellegrin, who at my request examined tho types of $E$. altipimis, for the information (received while this paper was passing through the press) that Valenciennes had correctly counted the anal rays, but that the figure was in this respect incorrect.

[^20]:     Raf.).

[^21]:    ＊In hallucutus the tail is grizzled drabby or grizzled buffy aloore and laterally for about half its length，the under surface lexcept the extreme bate）and end being black or biacki－h．The deseniption given in the Catalogue of Marsupials was based on imperfect specimens．

[^35]:    * A comparison of the measurements of Pt. lencopterus and pseluphon is perfectly fair, since the skulls of these two species are precisely of the same size (and indeed so similar also in other respects as to differ only in trivial details). Sliulls measured, 1't. lencopterus, B.M. ( 0.2 .1 .14 .3 , and (in parentheses) I't. pselaphon, B. II. 94.7.3.2: grathion to back of zygomatic: process of squamosal 54 mm . (54) ; z) gematic breadth 38 (37) : acro-s postero-external corners of alveoli of $\mathrm{m}^{3}-\mathrm{m}^{2} 19$ (19) ; across alveolar borders between $p^{3}$ and $p^{4} 15 \cdot 6(15 \cdot 8)$; hreadth of patate between imer sides of $\mathrm{m}^{2}-\mathrm{m}^{2} 12.5(13)$; between postero-internal corners of $\mathrm{P}^{4}-\mathrm{p}^{4} 10 \cdot 8$ $(11 \cdot 2)$; between $\mathrm{p}^{3}-\mathrm{p}^{3} 9 \cdot 8(9 \cdot 7)$.
    $\dagger$ Measurements, by 2 oniometer, of ancle formed by alveolar margin (front of $p^{3}$ to back of $m^{1}$ ) and tangent to upper and lower edges of orbit:-Pt. pselaphon (B.M. 94.7.3.2) 45:, Pterulopex atruta (68.1.5.9; type) $32-: 33^{\circ}$, Pt. leucopterus ( $6^{\circ} .1 .14 .3$ ) $2=0$, Pt. giganteus lencocephalus (45.1.8.274; Nepal) $25^{\circ}$.-Miller wites (op. cit. p. 61) that the orbits of Pteralopex are "strongly upturned," i. $\ell$. more so than in "Desmolopex," and lays sume stress on the supfused three stages of the po-ition of the orbits as marked by Pteropus worbits less upturned), Desmalopen: (more upturned), and Pteraloper (strmely uptumed), this. heingr one of his arguments for the alleged internediate position of Itesmaloprx hetween Pteropus and Pteralopes. The true facts are those shown by the measurements giren above and rerified by an instrument still finer than a goniometer, namely, the eye, that Pt. lencopterus duts not differ in this respect from I't. gigonters: and that the orbits of I'teralopeat are even slightly less uptumed. Miller's mistake is, however, jerfectly

[^36]:    excusable ; it really looks as if the orbits of Pteralopex reere more directed upward than in l't. leucopterus. The reason is this:- Owing to the exces-ively heary canines of l'teralopex, the alveolar border, in the usual position of the skull (lower jaw removed, sliull resting on a horizontal plane), is much more ascending in postero-anterior direction than in Pt. lencopterus; if, however, the two skulls are kept the one above the other, and with their alveolar borders parallel, it is very easily seen that the orbits are less upturned in Preralopex than in $P t$. leucopterus.

[^37]:    * I com-ider Pt. insularis (Puck atull, Carolines) and Pt. phaocephetus (Mortlock, Carolines) somewhat aberant members of the l't. p'stor, heme group.
